- Water-soluble lubricant, such as K-Y Jelly.
- Vaginal speculum.
- A minute timer.
- Vaginal sidewall retractors or glove to place over the speculum (to prevent injury to vaginal sidewalls in patients with redundant vaginal walls; see the "Technique" section of Chapter 151, Pap Smear and Related Techniques for Cervical Cancer Screening, for instructions on how to retract sidewalls with a "homemade" device).
- O-ring supply for some older cryo units. These are round rubber washers that attach at the base of the probe tip. They may crack over time, which could result in leakage of the refrigerant at the joint between the probe and the rod tip. They are easily and quickly replaced by simply removing the old one and sliding on the new one.

#### **PRECAUTIONS**

- Verify the patient is not pregnant before the procedure. A good history is usually adequate, but if in doubt obtain a pregnancy test. Although it is unlikely that there would be any harm, it is best to avoid cryotherapy in the pregnant patient.
- Be certain that vaginal walls are away from the cryotip to avoid freezing these tissues.
- Check the pressure in the tank to ensure it is adequate. The gauge dials are generally self-explanatory.

# PREPROCEDURE PATIENT EDUCATION

 Provide the patient with a patient education handout (see the patient education handout available online at www. expertconsult.com).

**Figure 138-3** Older cryotherapy tips with endocervical nipples longer than 5 mm should be avoided.

- Discuss the risks, the benefits, and the possible complications of cryotherapy.
- Before the procedure, review the indications with the patient.
- Obtain written informed consent.
- Confirm that this patient is willing to return for follow-up.
- Update the menstrual history and do a pelvic examination if one has not been done within the previous few months.
- Verify the patient is not pregnant; perform a pregnancy test if there is any doubt.
- Confirm the biopsy report and note any area where disease is concentrated to ensure that the cryoprobe readily covers the area.
- Premedicate the patient on her arrival to the office (if appropriate) with ibuprofen 800 mg or another nonsteroidal anti-inflammatory drug (NSAID) to reduce cramping that may occur with the procedure (if not already taken). For maximum effectiveness, the NSAID should be taken approximately 30 to 60 minutes before the procedure.

#### **PROCEDURE**

# **Prepare Equipment**

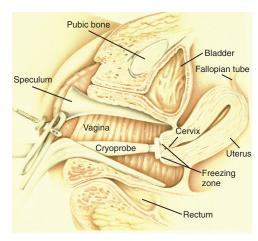

- 1. Ensure that the tank has adequate pressure; for most tanks the needle on the pressure gauge will be in the "green zone."
- 2. Ensure that the O-ring (the small rubber washer) at the base of the probe tip is intact, if applicable (mainly on older units).
- 3. Select the proper size and shape of probe tip. If the 19-mm tip covers the entire lesion and the entire transformation zone, it can be used. If all areas are not covered, use the larger, 25-mm tip. If the lesion is near the os or extends slightly (<5 mm) into the os, use the conical tip. If the lesion and squamocolumnar junction are well out on the ectocervix, a flat probe tip may be more appropriate to use. Avoid tips with long extensions because these may cause cervical stenosis (see Fig. 138-3).
- 4. Select the proper size vaginal speculum; the entire cervix and transformation zone must be well visualized, so consider using the largest speculum the patient can tolerate.

# **Prepare the Patient**

- 1. Place the patient in a comfortable dorsal lithotomy position in stirrups.
- 2. In select cases, consider using a submucosal cervical injection with lidocaine (see Chapter 149, Loop Electrosurgical Excision Procedure for Treating Cervical Intraepithelial Neoplasia). Some clinicians use topical anesthetics, but unless they are in place for 20 to 30 minutes they have little effect.
- Insert the speculum. If necessary, use a speculum cover or vaginal sidewall retractor to prevent vaginal injury in those with redundant mucosa.

#### **Perform Cryotherapy**

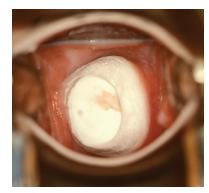

- Apply water-soluble lubricant (e.g., K-Y Jelly) to the cryoprobe tip.
- 2. Turn on the gas valve (pressure gauge in the "green zone").
- 3. Apply the probe firmly to the cervix and begin freezing by pulling the trigger or pushing the freeze button. The tip will adhere in about 3 to 5 seconds (Fig. 138-4). After the tip adheres, pull back slightly. Avoid the tendency to push in on the probe, which stretches the uterosacral ligaments and causes discomfort. Pulling back slightly will cause the vagina to "billow out," reducing the likelihood of the probe sticking to the sidewalls.
- 4. Watch the probe tip carefully to monitor the rim of ice. A 5- to 7-mm ice ball around the perimeter of the tip is required for cellular destruction (Fig. 138-5). This formation usually takes at least 3 minutes. A *timed freeze alone is not recommended* because the size of the tip used, the amount of cervical vascular-

**Figure 138-4** Proper application of the cryotip to the cervix.

ity and fibrous tissue, and the pressure in the nitrous tank all alter the amount of time required to form the 5- to 7-mm ice ball. In the majority of cases, *at least* a 3-minute freeze is used, after which the cervix is inspected to judge the size of the ice ball around the tip. If there is any question, continue the freeze. "Overfreezing" generally does not cause a significant problem.

- 5. When the ice ball around the probe tip reaches 5 to 7 mm, defrost by pushing the defrost button (on most machines) or releasing the freeze button. The probe tip will detach in about 15 seconds. Do not try to pull the probe off until it has thawed because that may result in laceration of cervical tissue. (The "active" defrost requires that the gas be left on—do not turn off the gas valve on the tank itself. A "passive" defrost takes at least 5 minutes just for the probe to release from the tissues.) If the probe does not easily release, check to be sure no one has turned off the gas. Switch back and forth between freeze and defrost. Sometimes the valve can stick.
- 6. Allow for a complete thaw of the cervix, which is seen when the cervix resumes a normal pink color. This may take 8 to 10 minutes. The patient often feels "flushed" during this period. Now, refreeze; the second freeze may take less time. Again, a 5- to 7-mm ice ball is required. A rapid freeze, slow defrost, and rapid refreeze technique has been shown to be the most efficacious method of treatment.
- 7. Thaw as described previously.
- 8. Remove the speculum and turn off the tank.
- Have the patient sit up slowly to avoid any vasovagal symptoms, such as lightheadedness or flushing. These may occur up to 10 minutes after completing the procedure.

**Figure 138-5** Appearance of the cervix immediately after cryotherapy. (Courtesy of John L. Pfenninger, The Medical Procedures Center, PC, Midland, Mich.)

- 10. Give the patient follow-up information. She will have a profuse, watery or blood-tinged discharge for 2 to 4 weeks. The next Pap smear should be scheduled for 6 months after this procedure (see the sample patient education handout online at www.expertconsult.com).
- 11. Consider prescribing a vaginal cream that aids in healing the cervix and potentially decreasing the discharge. Such a cream was previously available as Amino-Cerv Vaginal Crème, but it is no longer offered. It now must be compounded with the following ingredients:

 Urea
 8.34% (6.672 g)

 Sodium propionate
 0.50% (0.4 g)

 Methionine
 0.83% (0.664 g)

 Cysteine
 0.35% (0.28 g)

 Inositol hexanicotinate
 0.83% (2.988 g)

Ingredients are buffered to pH of 5.5 in a water-miscible emollient cream base to make 80 g. Prescribe one vaginal application at bedtime for 2 weeks.

#### **COMMON ERRORS**

- The patient may experience vasovagal symptoms after the procedure; avoid this by having the patient sit up slowly and rest a while before standing. Caution her to sit down immediately if she feels lightheaded.
- The anticipated postprocedure copious vaginal discharge can be mistaken for cervicitis.
- Turning off the gas at the tank before the probe has been released from the cervix.
- "Timing" the application as the sole criterion for the length of freeze. The size of the ice ball is the most important factor.
- Not emphasizing adequately to the patient that there will be a copious discharge but that this temporary inconvenience is worth it to avoid other, more severe complications associated with other methods of treatment.

#### COMPLICATIONS

- Vaginal mucosal injury is possible; avoid this by being certain
  that the cryoprobe does not touch the vaginal sidewalls. Use a
  speculum cover or vaginal wall retractors if necessary. If small
  areas are frozen, there are usually no significant adverse outcomes.
  If it appears that large areas of mucosa are being frozen, stop
  the procedure, take measures to protect the sidewalls, and start
  over.
- Pain and cramping may occur during cryotherapy; medicate
  patients with an NSAID about 30 to 40 minutes before the procedure. On rare occasions an anxiolytic may be helpful. In an
  especially anxious patient, consider a mucosal block. Avoid
  aggressive pulling on the cryoprobe during freezing because this
  may cause more intense cramping.
- The *profuse watery discharge* that follows cryotherapy is the most unpleasant consequence. It usually begins within the first day or two and lasts at least 2 weeks. The compounded cream noted earlier may help and may be used for a total of 4 weeks. Do not confuse this discharge, which always happens, with an infection.
- A cervicitis is possible after therapy. If the discharge is not improving after 2 weeks, consider oral metronidazole.
- A pelvic inflammatory infection is extremely rare. Consider it if there is extreme pelvic tenderness and fever.
- Should the patient surprisingly start her period within 4 to 5 days
  of cryotherapy, she may retain menses, causing severe discomfort.
  The cervix can be probed with a cotton-tipped applicator, which
  will usually release the blood.
- A very rare complication is *cervical stenosis*; using the proper probe tip should prevent this. Avoid any cryotip with projections greater than 5 mm.

- Asymmetric freeze of the cervix. If the cervix is very irregular in shape, consider freezing in segments, starting with the small, slightly nippled tip, then use the flat tip to cover the remaining areas.
- Treatment failure. Close follow-up is essential.

It is important to reassure the patient that there have been no documented long-term follow-up complications with future pregnancies after cryotherapy treatment.

#### POSTPROCEDURE MANAGEMENT

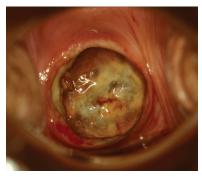

See the patient education handout available online at www. expertconsult.com.

- 1. Give the patient written follow-up information. She will have a profuse, watery or blood-tinged discharge for 2 to 4 weeks.
- Consider a compounded cream to decrease the discharge (see earlier discussion). A peri-pad is needed for a few weeks.
- 3. Regular bathing is acceptable. Showers are preferable over baths
- 4. Tampons should be avoided because they can irritate the friable cervix and cause bleeding.
- 5. Intercourse should be avoided for 2 to 3 weeks to allow adequate cervical healing and to prevent infection.
- 6. A follow-up Pap smear should be performed 6 months after cryotherapy, which allows adequate repair time of the cervical tissues. If that Pap smear is normal, it should be repeated in another 6 months. Colposcopy or human papillomavirus DNA testing may be performed along with either of these Pap tests, and may be especially useful if the patient had an initial high-grade lesion (see the American Society for Colposcopy and Cervical Pathology Guidelines in Appendix K). If follow-up laboratory results are normal, routine Pap examinations are resumed. Most recurrences occur within the first year after cryotherapy. If any of the postcryotherapy test results are abnormal, a complete reevaluation should be performed, including colposcopy, biopsy, and especially endocervical sampling. The cervix will have an altered appearance after cryotherapy, taking up to 4 months to return to a totally normal appearance (Figs. 138-6 to 138-10).

**NOTE:** Although some authors previously recommended bringing a patient back to the office after 2 to 7 days to "débride the cervix" to reduce the discharge, this procedure has been found to be of little or no value.

### **PATIENT EDUCATION GUIDES**

See the patient education and patient consent forms available online at www.expertconsult.com.

# CULDOCENTESIS (COLPOCENTESIS)

Steven H. Eisinger

Culdocentesis is a procedure for female patients designed to detect and sample free fluid in the peritoneal cavity. The classic application of this test is for the diagnosis of hemoperitoneum due to ruptured ectopic pregnancy, but it can also be used to detect acute pelvic inflammatory disease and to sample ascites. Modern imaging modalities, such as ultrasonography, have greatly reduced the need to perform culdocentesis, but occasionally in an emergency or where imaging resources are unavailable, culdocentesis can be extremely useful—even life-saving.

#### **ANATOMY**

The cul de sac is the lowest point in the abdominal cavity of a woman (when upright). The tissue septum between the posterior fornix of the vagina and the posterior cul de sac consists of vaginal mucosa, peritoneum, and little else. It is about 1 cm in thickness and contains no major blood vessels or organs. Thus, a needle introduced from the vagina into the cul de sac can easily access free fluid in the peritoneal cavity (Fig. 139-1).

## **INDICATIONS**

# **Ectopic Pregnancy**

Ruptured ectopic pregnancy is the classic indication. Signs and symptoms of ruptured ectopic pregnancy include amenorrhea, abdominal pain with rebound tenderness, vaginal bleeding, shoulder pain, and a positive pregnancy test. Hemodynamic instability and acute anemia may be present. On speculum examination the posterior fornix of the vagina may bulge into the vagina from the weight of the blood behind it. This 3-minute test can offer definitive proof of hemoperitoneum requiring immediate surgery.

#### **Acute Salpingitis**

Acute salpingitis can also be diagnosed by culdocentesis. This is the only means, short of abdominal surgery, to obtain pus from within the abdominal cavity for diagnosis and culture.

## Other

Ascitic fluid may be sampled for analysis such as for cytology for ovarian cancer, or even for therapeutic withdrawal.

#### **CONTRAINDICATIONS**

#### **Absolute**

A mass (e.g., a neoplasm, an abscess, an endometrioma, or an unruptured ectopic pregnancy, whose rupture could be harmful) in the cul de sac is an absolute contraindication.

#### Relative

Severe, fixed retroversion of the uterus is a relative contraindication since culdocentesis may be unsuccessful because the cul de sac is obliterated and the needle will strike the corpus of the uterus.

#### **EQUIPMENT AND SUPPLIES**

The equipment for culdocentesis is simple and should be available in any emergency department or medical office with gynecologic capabilities (Fig. 139-2). The following are required:

- Speculum
- Single-tooth tenaculum
- 10- or 20-mL syringe (a three-finger control syringe will allow aspiration with one hand)
- 20-gauge spinal needle or a 3-inch needle extender with a 20-gauge needle attached
- Sterile swabs or sponges
- Ring forceps
- Antiseptic solution
- Local anesthetic (optional)

The instruments should be sterile and gloves should be used to perform the procedure. Face mask and drapes are unnecessary.

### **PRECAUTIONS**

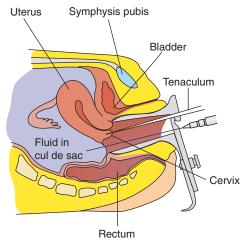

Universal blood precautions should be observed.

# PREPROCEDURE PATIENT EDUCATION

Verbal discussion is recommended. A procedure consent form should be completed. The listed risks should include bleeding, bowel perforation, rupture of a cyst, infection, and failure to detect blood (or fluid).

#### **PROCEDURE**

- 1. Perform a standard pelvic examination before the procedure. During the speculum examination, vaginal cultures may be obtained or other tests performed. A bulging of the cul de sac into the posterior fornix of the vagina is a finding suggestive of the presence of intraperitoneal fluid. It is important to detect fixed masses in the cul de sac, or fixed retroversion of the uterus, both of which contraindicate culdocentesis.
- 2. Position the patient. After first obtaining orthostatic vital signs allow the patient to stand or sit up for a minute before the procedure to permit blood to collect in the cul de sac. The procedure may be performed on any regular examination table with stirrups. The head and shoulders should be slightly raised.
- Place the speculum. A medium Graves speculum is suitable for most patients. Open it widely with the blades deeply placed in

**Figure 139-1** Midline sagittal view of pelvis during culdocentesis showing anatomic relationships and position of instruments. (Redrawn from Eisinger SH: Procedures in family practice: Culdocentesis. J Fam Pract 13:95–101, 1981.)

the anterior and posterior vaginal fornices above and below the cervix. This placement will expose the posterior fornix below the cervix and stretch it taut, making the needle puncture easier.

- 4. Cleanse the vagina with a suitable antiseptic solution.
- 5. Grasp the cervix with a tenaculum (Fig. 139-3). The tenaculum may be placed vertically or horizontally on the anterior or posterior lip, as the clinician desires. One milliliter of local anesthetic injected into the tenaculum site before placement is optional.
- 6. Choose the puncture site. Manipulate the cervix gently with the tenaculum by pulling either in and out or up and down. This maneuver will identify the line of reflection where the mucosa sweeps off the cervix and crosses or covers the cul de sac. The needle puncture site should be about 1 cm below this reflection, in the midline.
- 7. Administer anesthesia. This step is optional. Culdocentesis is usually perceived as quite painful. Some clinicians recommend

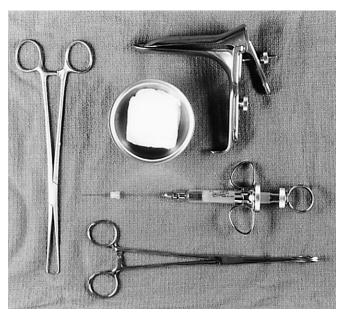

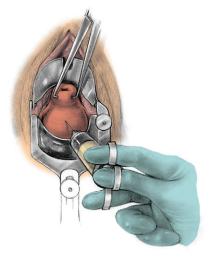

Figure 139-2 Equipment required to perform culdocentesis.

**Figure 139-3** Operator's view of culdocentesis. (From Eisinger SH: Procedures in family practice: Culdocentesis. | Fam Pract 13:95–101, 1981.)

injecting a small amount of local anesthetic into the mucosa at the puncture site. Alternatively, intravenous medication such as midazolam or hydromorphone may be given. The patient should be reassured that although the pain may be sharp, it will last only for a few seconds.

- 8. Make the puncture. Elevate the cervix in the vagina with the tenaculum to expose and stretch the mucosa of the posterior fornix. A small amount of air (1 to 2 mL) may be placed into the syringe before the puncture. The needle should be held approximately horizontal. Make the puncture itself with a bold, smooth movement, inserting the needle 3 to 4 cm through the mucosa, in the midline.
- 9. Inject the air in the syringe. Usually the air passes freely, and sometimes it can be heard bubbling through fluid. If the air does not pass freely, the needle tip is in a solid organ such as the uterus, and should be repositioned. Some practitioners may choose not to inject air.
- 10. Aspirate by pulling back on the syringe plunger. If blood or fluid fills the syringe, stop when it is full. If no fluid is obtained, then a second or even third attempt may be made at a slightly different angle or location.
- 11. Terminate the procedure when fluid is obtained, or when three attempts fail to yield any fluid.
- 12. Examine the fluid from the cul de sac. Observe free-flowing blood for several minutes for clotting because this may indicate a traumatic tap. Blood-tinged or frankly bloody fluid should be spun for a hematocrit. Clear or turbid fluid should be examined microscopically, and cultures, both aerobic and anaerobic, should be obtained. Fluid can also be sent for cytology if indicated.
- 13. A brief handwritten note or dictated paragraph in an operative note will suffice for documentation.

# SAMPLE OPERATIVE REPORT

Indication: Suspected ruptured ectopic pregnancy.

Procedure: Informed consent was obtained. Speculum placed allowing good visualization of the cervix and vagina. Area cleansed with iodine swabs. 2 mL of 1% lidocaine injected at aspiration site. Culdocentesis performed with 20-gauge spinal needle with insertion in the posterior fornix. First stick obtained 10 mL of free-flowing, nonclotting, bloody fluid with hematocrit of 20%. Patient tolerated procedure well with no signs of hemodynamic instability.

#### **COMMON ERRORS**

The most common error is incorrect angle or depth of needle puncture. This results in a failure to obtain fluid. This is corrected by repositioning the needle.

#### **COMPLICATIONS**

Complications of culdocentesis are rare. Bowel may be punctured on occasion. This usually resolves without sequelae. Puncturing a neoplasm or abscess is an unlikely possibility. Intra-abdominal bleeding is unlikely as long as the needle is kept in the midline, away from the great vessels of the pelvis. The most serious complication is a confusing result that prevents necessary treatment or leads to unnecessary intervention.

# POSTPROCEDURE MANAGEMENT

Vaginal bleeding is usually minimal and stops quickly. Patients should be provided with appropriate postprocedure instructions related to the diagnosis made as a result of the procedure (e.g., pelvic infection, ectopic pregnancy).

#### INTERPRETATION OF RESULTS

Blood obtained from the cul de sac should be tested for clotting and hematocrit. Pooled blood taken from within the peritoneal cavity is usually defibrinated and will not clot. However, in exceptional cases bleeding from a ruptured ectopic pregnancy is so brisk that the blood has not had time to become defibrinated and will therefore clot in the syringe. Peritoneal fluid may appear bloody even with a very low hematocrit. As a rough rule, a hematocrit below 15% suggests slight bleeding or a bloody tap, whereas a hematocrit over 15% indicates hemoperitoneum and confirms a surgical emergency.

Pus or turbid fluid should be Gram stained and cultured. White blood cells and bacteria may be noted. Appendicitis and pelvic inflammatory disease can cause a turbid exudate.

Clear fluid may result from a ruptured cyst, ascites, or normal peritoneal fluid.

Somewhat less than half the time no fluid can be obtained despite multiple taps. This phenomenon should be referred to as a *dry tap*, not a negative tap. No diagnostic assumptions should be made on the basis of a dry tap.

# **HYSTEROSCOPY**

Stephen A. Grochmal • Lydia A. Watson • Dale A. Patterson

Hysteroscopy is one of the oldest endoscopic procedures described in the medical literature and was first performed in 1807 by Bozzini. Unfortunately, few gynecologists and even fewer primary care physicians actually perform office hysteroscopy today. The hysteroscope is an extremely valuable tool for viewing the endocervical canal and uterine cavity, and hysteroscopy is now recognized as the method of choice for diagnosing, sampling, and treating intrauterine disease. Hysteroscopy provides an immediate direct visualization of the topography and contents of the uterine cavity, resulting in a more accurate diagnosis than that obtained from a dilatation and curettage (D&C) or blind endometrial biopsy. More important, a hysteroscopic inspection increases the accuracy of diagnosis when there is an abnormally shaped endometrial cavity or other pathologic condition present. Visually directed biopsies (via hysteroscopy) are preferable to D&C, especially for focal rather than global disease. Direct visualization provided by the hysteroscope confirms that the suspicious pathology has been sampled appropriately. Hysteroscopy can be performed in the office or in an operating room and typically is most easily accomplished when performed during the proliferative phase of the menstrual cycle, when the endometrium is the thinnest.

#### **ANATOMY**

The uterus is a muscular organ that is partially covered by peritoneum. The cavity of the uterus is lined by the endometrium. The uterus resembles a flattened pear in shape and consists of two major but unequal parts: an upper triangular shaped portion referred to as the body or corbus and a lower fusiform or cylindrical portion, the cervix. The demarcation line of these two portions is known as the isthmus. The anterior surface of the uterus is practically flat while the posterior surface is distinctly convex. The fallopian tubes emerge from the cornua of the uterus at the junction of the superior and lateral margins. The visible openings of the fallopian tubes are referred to as ostia. The upper or "top" portion of the uterus between the points of insertion of the fallopian tubes is called the uterine fundus. The cervical canal openings are called the external os and the internal os. The external os protrudes into the vaginal vault. The internal os is an important anatomic landmark during hysteroscopy because it marks the boundary between the uterine cavity and the endocervical canal, the location at which the main blood supply, the uterine arteries and veins, enters the uterus. Manipulation of the scope during hysteroscopy should cease when this landmark is reached. Vigorous operative procedures, including an unsuspected perforation during cervical dilation, in this area may result in excessive bleeding.

The wall of the body of the uterus is composed of three layers: (1) the outermost layer, the *serosa*, (2) the middle and thickest layer, the *myometrium*, and (3) the innermost portion, which lines the entire uterine cavity, the *endometrium*. The endometrium is a thin, pale pink, velvet-like membrane normally measuring in thickness from 0.5 mm to 5 mm, depending on cyclic changes that occur throughout the reproductive life of a woman. The endometrium is

perforated by a large number of tiny openings, referred to as *uterine gland ostia*, which are easily visualized during a hysteroscopy.

Hysteroscopic findings should be described schematically, mentioning both negative and positive findings at the different levels of anatomy of the uterine cavity: cornua and tubal ostia, fundus, isthmus, internal cervical os, and the endocervical canal. A description of the appearance of the endometrium and endocervical mucosa should also be included.

#### **INDICATIONS**

- Unexplained abnormal uterine bleeding (pre- or postmenopausal)
  - Endometrial polyps
  - Submucous leiomyoma
  - Hyperplasia/malignancies
  - Endometritis
  - Adenomyosis
- Evaluation of selected infertility cases
  - Abnormal hysterosalpinogram (HSG)
  - Foreign body (e.g., lost intrauterine device [IUD])
  - Uterine adhesions (Asherman's syndrome)
  - Occluded tubal ostia
- Repeated pregnancy loss
  - Recurrent miscarriage
  - Abnormal uterine cavity (i.e., septum or other uterine anomaly)
  - Retained products of conception
- Preprocedural evaluation of uterine cavity (i.e., endometrial ablation [any method])
- Visually directed insertion of tubal occlusion contraceptive device
- Essure microinsert hysteroscopic sterilization procedure (see Chapter 148, Insertion of Essure [Hysteroscopically Assisted Female Sterilization])
- Adiana permanent contraceptive system (see Chapter 148, Insertion of Essure [Hysteroscopically Assisted Female Sterilization])
- Localization of lost intrauterine device

# **CONTRAINDICATIONS**

# **Absolute**

- Cardiac or pulmonary instability
- Acute pelvic infection

#### **Relative**

- Pregnancy
- Coagulopathies: idiopathic thrombocytopenic purpura (ITP), von Willebrand's disease
- Previous uterine perforation or recent surgery or synechiae
- Known cervical or uterine carcinoma
- Morbidly obese patients
- Acute uterine bleeding

**Figure 140-1 A,** Diagnostic hysteroscopes with continuous-flow outer sheaths. The fenestrations on the distal tip of the sheath improve circulation of the liquid distention media. When using  $CO_2$  distention, a single-flow sheath may be preferable. **B,** Example of a diagnostic rigid hysteroscope and continuous-flow operating sheath with an operating channel used to pass a biopsy forceps or other instrumentation.

# **EQUIPMENT**

In order to perform hysteroscopy safely the mind set of the physician should be the same, whether the procedure is performed in the office or in an operating room. The choice of equipment is important, especially if the physician plans to perform "operative procedures" after gaining proficiency with simple diagnostic hysteroscopies.

The *basic* hysteroscope is a simple rigid (solid rod lens) device (Fig. 140-1). The diameter of the scope preferably is no greater than 5 to 5.5 mm when the introducing sheath is over the scope (used to protect the scope from breaking and provides a channel for continuous flow for fluid distention or an instrument). Size is important because the smaller the diameter of the scope, the less cervical dilation is required, and the more comfortable the procedure is for the patient. The angle of view for the scope is commonly 0 degrees, which provides a panoramic view once inside the uterine cavity and is an ideal all-around hysteroscope. Some surgeons prefer a 30-degree view with a more limiting, downward-looking vista.

Currently the most common device used is the *flexible* hysteroscope (Fig. 140-2). The flexible distal tip can improve maneuverability once inside the uterine cavity because of the ability to deflect the distal tip from 90 degrees to over 120 degrees. These flexible scopes are small in diameter (3.5 to 5 mm), do not require an outer sheath, and possess an operating channel, and the latest generations

**Figure 140-2** Flexible small-diameter hysteroscopes are easy to manipulate and are comfortable for patients but may lack a large-diameter operating channel for the passage of biopsy instruments, tubal sterilization inserts, or other procedure instrumentation. (Courtesy of Olympus Surgical America.)

**Figure 140-3** Technologic advances in electronics and hysteroscope designs have produced "all-in-one" systems that contain a camera controller, light source, documentation digital photo/video recorder, and, in this example, a flexible hysteroscope. These systems are portable and have a small "footprint," allowing them to fit easily on a countertop. (Courtesy of VisionSciences, Inc.)

have moved from fiberoptic bundle technology to digital chip-onthe-tip camera sensors (Fig. 140-3).

All newer flexible hysteroscopes are designed to accommodate instrumentation for office procedures such as the Essure sterilization. These flexible scopes are more costly than a rigid system. The high initial cost may be offset by the increased reimbursement achieved with the variety of procedures that can be performed with the flexible scope.

A *light source* ranging from 100 to 300 watts is needed. A halogen light is acceptable, but a xenon light source is preferred because it emulates natural daylight and provides superior illumination of the uterine cavity.

In addition, a *simple grasping forceps*, *biopsy forceps*, and *scissors* will round out the special instrumentation necessary to perform simple operative procedures such as endometrial biopsy, polyp removal, and removal of retained IUDs.

An optional piece of equipment is a *video endoscope* (Fig. 140-4). A camera eliminates the need to look through the eyepiece of the hysteroscope and improves the working position, comfort, and visualization. It also allows the patient to partake in the procedure by watching simultaneously as the hysteroscopic evaluation is performed. Some vendors now produce systems with all these components in one stand-alone unit (Fig. 140-5).

Additional video equipment provides the ability to record and document the procedure so that photographic documentation of findings can be included in the patient's operative report. It also allows a physician to send detailed information back to a referring

Figure 140-4 Video cameras can directly attach to the eyepiece of the hysteroscope, dramatically improving visualization of the uterine cavity.

**Figure 140-5** New electronic equipment designs for office hysteroscopy have resulted in systems that allow the hysteroscope (in this case a flexible design) to connect directly to one unit, which contains the camera controller, light source, documentation recorder, and LCD monitor.

colleague. These pictures should be maintained as an integral part of the patient's chart.

Choose a distention medium. Uterine distention is crucial to the success of any hysteroscopic procedure. Most office hysteroscopic procedures are performed with saline.  $CO_2$  distention is mainly used for diagnostic hysteroscopy. Hyskon is difficult and "messy."  $CO_2$  is more difficult for the novice because of the tendency for troublesome gas bubbles to form, and it cannot be used if any bleeding occurs.

Sorbitol and glycerine are for electrical (bipolar) operative procedures. Saline, then, is the "consensus gold standard" for office hysteroscopy. It is safe, physiologic, and inexpensive. A gravity flow system can be used for the majority of diagnostic procedures, providing more than adequate uterine distention (Fig. 140-6). A method for monitoring the amount of fluid used to distend the uterus is needed. It is uncommon to have fluid and electrolyte complications if less than 1 L of fluid is used during the procedure. Commercial systems are available to control the flow and accurately record the fluid deficit during hysteroscopy. For short diagnostic procedures, the amount of fluid used to distend the uterus to 500 mL or less is sufficient. For slightly larger volumes, monitoring the amount of fluid used to distend the uterus and collecting the residual fluid in a pouched drape for subsequent measurement is an option. Carbon dioxide is also commonly used with few complications and low risks of complications (Fig. 140-7). Instructions on the use of both normal saline and carbon dioxide are noted later.

A standard tray for hysteroscopy includes instruments for anesthesia and cervical dilation (Fig. 140-8A and B):

- Antiseptic solution (e.g., povidine-iodine)
- Large cotton-tipped swabs
- Vaginal speculum (unhinged one side, open-sided Graves, or disposable illuminated types) (Fig. 140-8C)
- Cervical tenaculum
- Ring forceps
- Uterine sound
- Cervical dilators (see Chapter 136, Cervical Stenosis and Cervical Dilation)
- Topical 2% benzocaine
- Lidocaine without epinephrine 1% to 2% (optional but helpful); anesthesia can be accomplished with topical and local anesthetic
- 10-mL syringe with 4-inch needle extender and 25- to 27-gauge needle, or a dental syringe, if anesthetic is to be given into the cervix (see Chapter 149, Loop Electrosurgical Excision Procedure for Treating Cervical Intraepithelial Neoplasia, and Chapter 173, Paracervical Block)
- Endocervical curette

#### **PRECAUTIONS**

Poor visualization increases the risk of complications. Larger uteri may take a bit longer to achieve adequate distention. Plan on

Figure 140-6 Systems used to achieve distention of the uterine cavity during diagnostic hysteroscopy. **A**, A 1000-mL bag of saline with large-bore tubing used for gravity flow distention. **B**, A closed system designed to capture the outflow distention fluid. **C**, A simple pressure cuff used to increase flow of distention medium; it offers no control of intrauterine pressure. (**B**, Courtesy of Gynex.)

**Figure 140-7** Use of  $CO_2$  as a distention medium for diagnostic hysteroscopy mandates an appropriate device for instillation of the  $CO_2$  gas. Intrauterine pressure must be precisely maintained to avoid passage of distention media into the fallopian tubes and subsequently into the abdominal cavity. (Courtesy of Karl Storz.)

spending the amount of time needed with each patient to ensure adequate distention and visualization.

- Be aware that not all insufflators, light sources, and scopes are interchangeable. Mixing and matching may be dangerous. Check compatibility issues with your suppliers.
- A pregnancy test is advised in all reproductive-age patients prior to the procedure.
- Cervical cultures should be obtained for patients at high risk for pelvic infections before hysteroscopy is performed.
- Avoid hysteroscopy during menses or heavy bleeding if possible it is more difficult to see uterine contents and landmarks.
- As with any in-office invasive procedure, proper emergency resuscitation equipment and action plan should be readily available (see discussion of the Banyan kit in Chapter 220, Anaphylaxis).

# PREPROCEDURE PREPARATION

- The patient is best served if provided a *patient education* handout or pamphlet prior to the procedure.
- A consent form for diagnostic hysteroscopy with or without endometrial biopsies should be obtained.
- Document the last menstrual period, contraceptive method, and pregnancy test (if indicated) results on every patient.
- Preprocedure antibiotics are not required.
- Nonsteroidal anti-inflammatory drugs (NSAIDs) (e.g., ibuprofen 800 mg) administered 30 minutes before the procedure can significantly diminish the discomfort of the procedure.

# **PROCEDURE**

There are multiple variations of how to perform a hysteroscopy. The steps listed here are one such method.

- Throughout the procedure, attempt to maintain a sterile environment, especially with equipment and instrumentation that are inserted into the uterus. The vaginal component of the procedure is considered a "clean" field, but it is a good habit to maintain sterile technique throughout the entire procedure.
- 2. With the patient in dorsal lithotomy position and preferably on an electric-powered examination table, *perform a bimanual pelvic examination* to ascertain the size, shape, and position of the uterus. Failure to do this may result in a uterine perforation during cervical dilation or initial insertion of the hysteroscope.
- Insert a disposable illuminated vaginal speculum or a reusable open-sided Graves speculum.
- 4. Prep the cervix and vagina with antiseptic solution.
- 5. Insert a large cotton applicator under the cervix and *spray a small amount of topical 2% benzocaine* oral anesthetic on the cervix. The cotton applicator will absorb the anesthetic. Allow the applicator to remain in contact with the cervix as you talk to the patient and prepare your instruments. Remove the applicator.
- 6. Anesthetize the cervix. Using a dental-style cartridge syringe with ampules of 2% lidocaine (or other anesthetic) and a 25- to 27-gauge dental needle, place a minimum of 1 mL (maximum amount per quadrant is up to 2 mL) of anesthetic at the 3, 6, 9, and 12 o'clock positions of the cervix into the subserosal layer. (For detailed instructions, see chapters noted earlier.)
- 7. Grasp the anterior (or posterior, depending on uterine position) *lip of the cervix* with a tenaculum.
- 8. Perform an endocervical curettage (ECC) if indicated.
- 9. Sound the uterus to determine depth and direction of the central uterine axis.
- 10. Dilate the cervical canal. Using a set of silastic or metal graduated dilators, insert the os finder or a 3 mm dilator into the cervix, and, feeling for resistance, pass this through to the internal os, if possible. Continue progressive dilation up to a size 1 mm over the diameter of the hysteroscope. Dilation should be done slowly with a constant gentle pressure, especially in the nulligravid patient. Multiparous patients are generally easier to dilate. You may leave this dilator in the cervix to maintain patency as you reach for the hysteroscope. For stenotic patients, see Chapter 136, Cervical Stenosis and Cervical Dilation.
- 11. Remove the dilator.
- 12. The saline is suspended 60 cm above the uterus and will enter the cavity with a pressure of 45 mm Hg (see Fig. 140-6). The maximum uterine pressure via any distention method should

Figure 140-8 A, Typical instrument setup for office diagnostic hysteroscopy. B, Disposable office packs make procedure setup and clean-up simple. These packs contain all the necessary items required to perform an office hysteroscopy. C, Example of a disposable, self-illuminating LED, open-sided speculum. (B and C, Courtesy of OBP Medical, Inc.)

not exceed 70 mm Hg, which is below the capillary pressure of 100 mm Hg. Varying the height of the saline bag will alter this infusion pressure. If a pressure sleeve is placed around the bag of saline, additional pressure required to increase flow rate of the distention medium can be achieved by inflating the sleeve as needed. This is a useful technique in patients with a larger uterus or when a faster flow of distention medium is required to "clear" the field of view (see Fig. 140-6C).

If carbon dioxide is used, begin insufflation once the scope engages the external os. Use the instillation port on the scope at an initial rate of 30 mL/min. As the hysteroscope traverses the endocervical canal, the carbon dioxide will create a visual space ahead of the scope. Advance the scope only if the view is clear. The internal os is seen as a narrow constriction at the upper portion of the endocervical canal. Increase the carbon dioxide insufflation rate to 40 to 60 mL/min when the isthmus of the uterus is entered. The carbon dioxide insufflation must be critically controlled during the procedure. If the gas is instilled too quickly, obstructive bubbles of carbon dioxide will form. The maximum flow rate should not exceed 100 mL/min and a maximum pressure of 100 mm Hg. The risk of gas embolism is proportional to the flow rate of the infused gas. Embolization of small amounts of CO<sub>2</sub> is not dangerous, and over 50% of CO<sub>2</sub> hysteroscopies have some amount of carbon dioxide embolized.

If saline is used, the hysteroscope is inserted under direct visualization, advancing the scope slightly into the endocervical canal. Start the distention fluid (e.g., normal saline) flowing and continue to gently advance the scope until you feel a slight resistance. You are now at the uterine fundus. Pause to confirm that the distention fluid is flowing into the cavity. Using a continuous flow hysteroscope and a bag of saline hanging from an intravenous (IV) pole approximately 60 cm above the patient, the distention fluid flow rate will range between 125 and 200 mL/min with an average intrauterine pressure of approximately 45 mm Hg; this rate creates no problems. This flow rate may vary based on parameters such as the diameter of the tubing used, exact height of the IV pole, if suction aspiration is used on the outflow side of the hysteroscope, and if a pressure cuff is employed around the saline bag.

- 13. Withdraw the scope ever so slightly from the fundus and wait. As the distention fluid clears, the fundus will come into view. If you have successfully reached this point, the hysteroscopy is 75% complete and all that remains is the visual inspection of the cavity. Remember, failure to achieve adequate distention and repeated attempts to do so increase the risk of procedure failure and complications. If the uterus cannot be easily distended, consider stopping the procedure. It is important to recognize when to stop!
- 14. *Inspect the uterine cavity*. Withdraw the scope slightly and look at the fundus. Move the hysteroscope to the patient's right, then left. You can move the scope in or out, up or down, and rotate it to achieve the best views (Figs. 140-9 and 140-10). The central point of müllerian duct fusion projects down from the fundus. The cornua are located on both sides of this fused tissue. Evaluate the tubal ostia. Continue to withdraw the hysteroscope down into the lower segment of the uterine cavity. Visualize the anterior, posterior, and lateral walls of the cavity, maneuvering the scope ever so slightly when needed. Document

**Figure 140-9** Mobile tip at the end of the hysteroscope. (Courtesy of Olympus Corp., Melville, NY.)

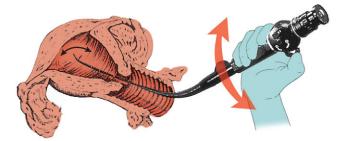

Figure 140-10 Hysteroscopic examination of the uterine cavity.

any findings with photo or video recording as the procedure is performed. Continue to withdraw the scope until a "ring" appears over the scope. This is the level of the internal os of the cervix and the start of the endocervical canal. It is an important landmark to document and confirm the completion of the uterine cavity inspection (Figs. 140-11 and 140-12).

- 15. Biopsy any suspicious areas. Remove stalked endometrial polyps with grasping forceps. Generally, any bleeding will stop on its own and no cautery or chemicals are needed. All biopsies are taken after a complete inspection of the uterine cavity and prior to terminating hysteroscopy. Bleeding from the biopsies, even minimal, may decrease visualization regardless of the distention medium selected. With CO<sub>2</sub>, this will decrease the view and may not allow re-entry into the cavity and require terminating any further observation. With saline, the clouding will dissipate as fluid continues to flow through the uterine cavity. The field generally clears, allowing the procedure to continue if necessary, but this may not always be the case.
- 16. Continue to withdraw the scope through the endocervical canal, observing and documenting when necessary. You have now completed what is referred to as a retrograde diagnostic hysteroscopy. Shut off the distention flow and remove the scope from the vagina. Remove the tenaculum and observe for any bleeding. Remove all other instrumentation and the procedure is complete.
- 17. Clean the scope.

Total fluid recovered:

18. Dictate an operative report.

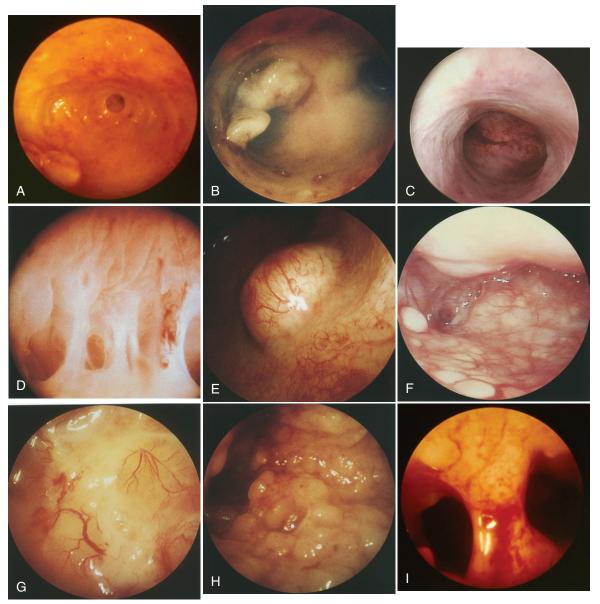

#### SAMPLE OPERATIVE REPORT

Preoperative diagnosis: Abnormal uterine bleeding Procedure performed: Diagnostic hysteroscopy with endometrial biopsies; endocervical curettage Postoperative diagnosis: Endometrial polyps, hypertrophic endometrium Surgeon: Dr. Assistant: (Dr.'s name, assistant's name, or none) Estimated blood loss: Nil Complications: None Findings: Total distention fluid instilled: Approx. 350 mL of normal saline

With the patient on the procedure table in dorsal lithotomy position and in Allen stirrups, the patient was prepped and draped for hysteroscopy. Bimanual examination revealed a normal size, anteverted uterus and no significantly palpable adnexal masses.

Approx. 300 mL

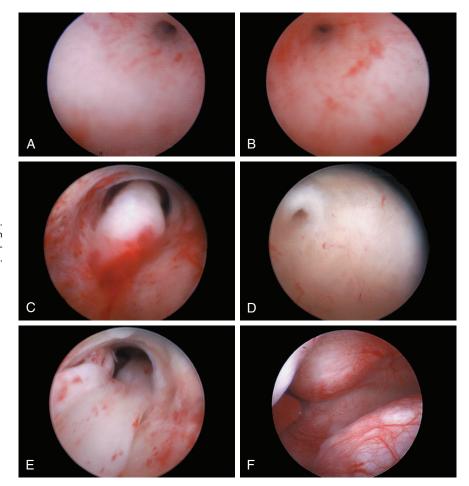

An illuminated speculum was inserted into the vagina and the cervix was cleansed with a Betadine solution. Topical bupivicaine (Hurricaine solution) was applied to the cervix and the run-off collected by a sponge stick. After waiting a few minutes for the topical

**Figure 140-11** Typical uterine anatomy and pathology seen during diagnostic hysteroscopy: Tubal ostium (normal) (**A**); benign polyp in right cornua of uterine cavity (**B**); atrophic endometrium (**C**); uterine adhesions (synechiae) (**D**); submucosal fibroid (**E**); benign endometrial hyperplasia (cystic) (**F**); endometrial hyperplasia (high risk) (**G**); endometrial cancer (**H**); uterine septum (side-by-side double-barrel shotgun appearance) (**I**).

anesthetic to take effect, an intrastromal cervical block was performed. Approximately 1.8 mL of 2% lidocaine without epinephrine per quadrant was instilled at 12, 3, 6, and 9 o'clock positions on the cervix with a 27-gauge needle and Tubex syringe. The anterior lip of the cervix was grasped with a single-tooth tenaculum and an endocervical curettage was performed, followed by uterine sounding. Progressive dilation of the cervix with graduated dilators was carried out up to 6 mm. The uterus sounded to 10 cm. Thereafter, a 30-degree hysteroscope with diagnostic/operating sheath was inserted into the uterus under direct visualization and gently brought to bear against the fundus of the uterus. Using a gravity flow saline distention, the uterine cavity was distended until a clear image was achieved. (Optional to mention: video footage or digital photos were taken.) The hysteroscope was withdrawn farther away from the fundus until both tubal ostia could be visualized; both appeared normal. As the hysteroscope was withdrawn farther down into the uterine cavity, the entire fundus and upper portion of the cavity were visualized. Inspection of the cavity did not reveal the presence

of any adhesions, submucous fibroids, or abnormal configuration. Of note were areas with visible large vessels coursing superficially beneath the thickened, hypertrophic endometrium. Multiple biopsies were taken with the biopsy forceps via the operating channel and individually marked according to their location. As the hysteroscope was withdrawn further, the level of the internal os was clearly identified. Three small endometrial polyps, the largest measuring approximately 0.5 cm, were seen. (Mention that a photograph or video was taken.) The hysteroscope continued to be withdrawn in a retrograde fashion under direct visualization through the endocervical canal, which was unremarkable. The hysteroscope was then removed from the vagina and the saline distention discontinued. Any residual fluid was evacuated from the vagina and the cervical tenaculum removed. No bleeding was noted from the cervix. Remainder of the instrumentation was removed from the vagina. The procedure was complete. Patient tolerated the procedure well and after a 15-minute recovery left the office feeling well and in good condition.

**Figure 140-12 A** and **B**, Fallopian tube. **C**, Endometrial polyp arising from fundus (seen on entrance into uterus). **D**, Fallopian tube. **E**, Attachment site of endometrial polyp at fallopian tube. **F**, Uterine fibroids.

#### **COMMON ERRORS**

- Attempting procedure with inadequate distention of the uterus.
- Performing the procedure under poor visualization. If the distention fluid is murky or bloody, stop until the field clears. Then proceed slowly. If the field is still cloudy, check your distention connection tubing and bag of fluid. If this problem continues, stop the procedure and reschedule the patient. You do not want to perforate!
- If you suspect a perforation, just stop. Remove all instruments.
  Place the patient in a semi-upright position and observe her for
  changes in vital signs, pallor, complaint of pain, or vaginal bleeding. Be prepared to consider a diagnostic laparoscopy. Most perforations are uneventful and the puncture closes readily, but
  always err on the side of caution. Repeat hysteroscopy can be
  performed in 6 weeks.
- Performing a biopsy prior to completing inspection of the entire uterine cavity may cause bleeding, thus clouding the visual field and resulting in the inability to complete the uterine cavity evaluation.

### **COMPLICATIONS**

- Cervical laceration secondary to forceful dilatation.
- Uterine perforation.
- Infection.
- Fluid overload (usually not a concern with diagnostic hysteroscopies since most require only 250 to 350 mL of distention medium).
- Complications related to carbon dioxide insufflation (if used) are rare with the use of a constant-flow insufflator. Acidosis and hypercarbia are rare events. Patients can experience shoulder

pain secondary to irritation of the diaphragm from the  $\mathrm{CO}_2$  in 2% to 5% of the cases. If the patient complains of shoulder pain, keep her lying flat and ask her to breathe deeply. The pain may last up to 20 minutes before dissipating.

- Inability to perform the procedure secondary to cervical stenosis
- Vasovagal reactions occur in less than 1% of patients, but physicians should be prepared to manage these reactions and symptomatic bradycardia.

# POSTPROCEDURE MANAGEMENT

- Keep the patient in a semi-upright position for about 15 minutes.
- Observe for any watery discharge or excessive bleeding.
- Suggest NSAIDs as needed for any postprocedure discomfort.
- Patient resumes normal activity within 4 to 6 hours.

# **POSTPROCEDURE PATIENT EDUCATION**

- Patients may notice mild cramping after the procedure. Reassure them that it is transitory and to use NSAIDs for relief.
- Some watery or blood-tinged discharge is normal for up to 2 to 3 hours. Instruct the patient to use a sanitary pad and to report any prolonged episodes of vaginal discharge, bright red bleeding, fever, or excessive abdominal pain.
- Instruct patients to avoid inserting anything in the vagina for 24 hours. They may resume intercourse after 24 hours.
- Patients generally will return to their daily lifestyle activities within 8 hours after the procedure with no restrictions on physical activity.
- Patients should call if there is any foul odor or discharge, which could signal an infection.

#### INTERPRETATION OF FINDINGS

- Abnormal uterine bleeding (AUB) is probably the most common symptom investigated by hysteroscopy. Endometrial biopsy or D&C can be carried out at the end of the hysteroscopic examination. The main causes of AUB are submucous myomas, endometrial polyps, endometrial atrophy, and postpregnancy metrorrhagia.
- Submucous myomas can vary in appearance. At times they have
  a regular, smooth surface covered by a homogeneous endometrium similar to that of the remainder of the uterine cavity. If
  there is extensive intracavitary progression, then the ensuing
  compressed endometrium may give rise to ulceration and necrosis
  near the apex of new growth. At times, the surface of the myoma
  appears lobulated, pearly white in color, and grooved with one or
  more large blood vessels (see Fig. 140-11E).
- Endometrial polyps are exophytic, usually sessile mucous lesions varying in shape, number, size, and appearance. Their surface is similar to that of the surrounding endometrium and soft in consistency upon contact with biopsy forceps or a hysteroscope. Pedunculated polyps have a variable length to their pedicle consisting of vascularized connective tissue. These lesions have cubic, short, cylindrical epithelium interspersed with hypertrophic blood vessels. Polyps can be associated with glandular endometrial hyperplasia and can remain latent for long periods (see Fig. 140-11B).
- Endometrial atrophy is a postmenopausal physiologic change that
  may cause bleeding. The hysteroscopic image is quite characteristic: since the endometrial mucosa is quite thin, it often appears
  transparent, revealing the underlying vascular structures. The
  presence of hemorrhagic petechiae is very typical. In severe endometrial atrophy the epithelium is smooth and pale, nearly white
  (see Fig. 140-11C).
- Postpregnancy metrorrhagia. In patients with postpartum or postabortal bleeding, hysteroscopy may be used to confirm evacuation or removal of all abortive debris from the uterine cavity. The overall appearance is that of an atrophic endometrium infused with hemorrhagic areas and petechiae along with dangling pedicles and fragments of benign, shredded endometrium.
- Intrauterine adhesions. Hysteroscopically, synechiae may be centrally or marginally located and may be classified as endometrial, myometrial, or connective fiber synechiae. Endometrial synechiae often grow from abortive tissue and create filmy adhesions, which are easy to remove. Myometrial synechiae appear "buttress"-like, usually marginally located throughout the cavity, and as distinct "organized" structures, and connective fiber adhesions often change the normal morphology and structure of the uterine cavity (see Fig. 140-11D).
- Uterine cavity septum appears as either arcuate (involves the fundus) or as an incomplete or complete septum. The latter two are generally discovered upon entry into the uterine cavity just past the internal os. The appearance is likened to looking at a double barrel shotgun head-on or a "pig's snout." The septum generally has the same appearance as the surrounding endometrium. The arcuate type is usually visualized as a bulge in the top of the fundus protruding downward into the uterine cavity. The surface area may appear more "atrophic" than the rest of the uterine cavity endometrium (see Fig. 140-111).
- Endometrial carcinoma and precursors. Abnormal uterine bleeding is the first symptom in over 90% of cases, so early detection is relatively straightforward if proper procedures are performed. In fact, 75% of endometrial cancers are diagnosed as stage I.

Hysteroscopic findings include the following:

Endometrial hyperplasia is a precursor of endometrial cancer. The
hysteroscopic appearance generally resembles normal glandular
epithelium, and the thickness of the mucosa can be determined
by pressing with the hysteroscope (see Fig. 140-11F).

- Low-risk endometrial hyperplasia (EH) often shows a specific pattern of widened glandular ostia with cystic-glandular formations about 1 mm in diameter. The same formation can be found in an endometrium of reduced thickness, where they indicate cystic atrophy. Aside from the cystic form, EH is characterized by a variety of other hysteroscopic changes such as increased endometrial thickness, nonhomogeneous endometrial regeneration, increased vascularization, presence of ciliated epithelium, cystic dilation, polypoid formations, irregularly arranged glandular orifices, and necrotic areas. If one or more of these elements are found, hyperplasia must be suspected and endometrial biopsies should be performed.
- High-risk endometrial hyperplasia (EIN) presents a varied hysteroscopic image with polypoid appearance and vascularization clearly evident. This vascularization takes on an arborescent appearance, sometimes described like a "corkscrew" in that it surrounds groups of glandular ostia. The appearance of the mucosa could be described as "cerebroid" due to the abnormal growth and vascularization, similar to the irregular surface of brain tissue (see Fig. 140-11G).
- Endometrial neoplasia. Hysteroscopy is an extremely reliable technique for the diagnosis of endometrial neoplasia. The hysteroscopic images are clear and so obvious that they are rarely confused with other lesions. In its initial stage, adenocarcinoma presents a germinative scenario, with irregular, polylobular, delicate excrescences, which may be bleeding or necrotic; vascularization is irregular or anarchic. In some instances, the involved area may be clearly demarcated from the normal endometrium. In other cases, it may be possible to see focal lesions, sometimes on the tubal cornua or sporadic implants throughout the uterine cavity (see Fig. 140-11H).

# **CPT BILLING CODES**

57505	Endocervical curettage, not with D&C
57800	Dilation; cervical canal, instrumental
58555	Hysteroscopy, diagnostic
58558	Hysteroscopy with biopsy of endometrium or polypectomy
	with or without D&C.
58559	With lysis of intrauterine adhesions
58560	With division or resection of intrauterine septum
58561	With removal of leiomyomas
58562	With removal of impacted foreign body
58563	With endometrial ablation, any method
58565	Hysteroscopic sterilization (Essure Adiana)

# **ICD-9-CM DIAGNOSTIC CODES**

- 182.0 Malignancy, corpus uteri except isthmus
- 182.1 Malignancy, isthmus of uterus
- 218.0 Submucous leiomyomas, uterus
- 210.0 Submideous felomyomas
- 218.1 Intramural leiomyoma
- 219.1 Uterine neoplasm, benign
- 233.2 Carcinoma in situ, unspecified part of uterus
- 621.0 Polyps, uterine
- 621.3 Hyperplasia of endometrium, unspecified
- 621.5 Adhesions, intrauterine (synechiae)
- 622.4 Stricture and stenosis of cervix
- 622.7 Mucous polyp of cervix
- 625.3 Dysmenorrhea
- 626.0 Absence of menstruation
- 626.2 Excessive or frequent menstruation
- 626.4 Irregular menstrual cycle
- 626.6 Metrorrhagia
- 627.0 Premenopausal menorrhagia
- 627.1 Postmenopausal bleeding

# DILATION AND CURETTAGE

Verneeta I., Williams • Sheila Thomas

Dilation and curettage (D&C) is a valuable diagnostic and therapeutic tool in the management of abnormal uterine bleeding (AUB) and pregnancy-related disorders. Endometrial biopsy techniques have replaced D&C in most diagnostic situations, and hysteroscopy (see Chapter 140, Hysteroscopy) is now often performed in place of the "blind" D&C when initial diagnostic and therapeutic interventions fail. When the operator is experienced and the proper ancillary personnel are available, the office D&C proves to be a very cost-effective and safe procedure for the patient. Otherwise, the procedure can be performed in the operating room. In many instances of abnormal bleeding, diagnosis is facilitated if the sampling is done just before an anticipated period (e.g., for anovulatory bleeding). Unless the procedure is pregnancy related, the clinician should ensure that the patient is not pregnant and should know the status of the Papanicolaou (Pap) smear before the surgery. In addition to this chapter, it would be helpful for the clinician to review Chapter 143, Endometrial

On reaching menopause all women should be informed about the risks and symptoms of endometrial cancer and strongly encouraged to report any unexpected bleeding or spotting to their physician.

# **INDICATIONS**

# **Diagnostic**

- To determine the cause of abnormal premenopausal bleeding that has not been corrected by medical management
- To determine the cause of abnormal premenopausal bleeding that occurs in women older than 40 years of age with inadequate endometrial biopsies
- To determine the cause of postmenopausal bleeding when endometrial aspiration is nondiagnostic
- To rule out cancer and adenomatous hyperplasia with atypia when complex hyperplasia (adenomatous hyperplasia) is found on endometrial biopsy
- When the endometrial lining (stripe) measures more than 5 mm on ultrasonography
- To determine the cause of significant uterine bleeding that is too excessive for an endometrial biopsy
- When a reliable pelvic examination is required but cannot be obtained to evaluate the internal organs before endometrial biopsy, and thus anesthesia would be helpful
- For a debilitated or apprehensive patient when endometrial biopsy cannot be performed
- When cervical stenosis cannot be resolved and prevents an office procedure
- When pregnancy-related causes are suspected for AUB
- When atypical glandular cells are reliably found and confirmed on Pap smear, but no cause is found in a less invasive work-up

# **Therapeutic**

- For removal of suspected endometrial polyp
- For removal of retained products of conception associated with postpartum infection or hemorrhage
- For removal of retained products of conception after an incomplete abortion
- For therapy of excessive hemorrhaging
- For use in combination with hysteroscopy

**NOTE:** Performing a D&C to resolve hormonally related AUB has been found to be ineffective.

#### Other

Elective termination of pregnancy (see Chapter 127, Pregnancy Termination: First-Trimester Suction Aspiration) is another indication for D&C.

# **CONTRAINDICATIONS**

#### **Absolute**

- Existence of comorbid medical conditions that are unstable (e.g., renal failure, active cardiac compromise)
- Desired viable intrauterine pregnancy

#### Relative

- The presence of an active pelvic infection
- Signs of a systemic coagulopathy (i.e., diffuse intravascular coagulation or unknown anticoagulation status)
- Uncertainty concerning the viability of an intrauterine pregnancy
- Patient's preference to defer procedure in anticipation of a spontaneous resolution of a miscarriage
- Prior history of uterine procedures and the development of Asherman's syndrome (i.e., endometrial synechiae)

**NOTE:** A D&C should be performed in the office only with a cooperative patient who has no other significant health risk factors and only if adequate resuscitation equipment is available.

# **EQUIPMENT**

See Figure 141-1.

- Sterile gowns (optional)
- Sterile gloves
- Sterile drapes
- Sterile sponge gauze
- Formalin bottles

Figure 141-1 A, Equipment used for dilation and curettage (*left to right*): sterile basin, 4 × 4 sterile sponge gauze, large obstetrics/gynecology applicators, weighted speculum, uterine sound, ring forceps, single-tooth tenaculum, curette, dental anesthetizing gun, 1.8 mL of 2% lidocaine with epinephrine, uterine dilators, leggings, and sterile covering. B, Suction device and tubing.

- Lens paper or Telfa pads for endocervical curettage and uterine curettage tissue
- Antiseptic cleansing solution
- Sterile bowl
- Suction hosing and apparatus with pump (for some situations, especially if significant bleeding or pregnancy related)
- Ring forceps
- Uterine sound
- Graves or weighted (Auvard) speculum
- Polyp (Stone) forceps
- Cervical dilators
- Kevorkian endocervical curette for endocervical curettage
- Curved and straight suction catheters (size 8 to 12 mm) when applicable
- Sharp uterine curette
- Intravenous (IV) needle, catheter, and tubing
- IV fluids (optional)
- A 20-gauge spinal needle and syringe, dental anesthetizing gun, or needle extender when local anesthesia (submucosal block) will be used
- Lidocaine 5 mL (2%) with epinephrine for submucosal block or 10 mL of lidocaine without epinephrine for paracervical block or equivalent

**NOTE:** Review Chapter 149, Loop Electrosurgical Excision Procedure for Treating Cervical Intraepithelial Neoplasia, for information regarding local anesthetic use (it is not needed if general anesthesia is given).

- Tenaculum
- Ultrasonography (optional)
- Pulse oximeter if IV sedation is given

#### PREPROCEDURE PATIENT EDUCATION

Each patient should be comfortable with the decision to perform a D&C. All questions regarding the procedure, alternatives, and risks should be explained carefully so the patient can give informed consent (see the sample patient consent form online at www. expertconsult.com). If performed in the office with sedation, appropriate knowledge and equipment must be available for possible complications and resuscitation. A nurse should be available throughout the procedure to aid with preparing the patient for the procedure, injecting IV medications, and handling equipment, and to provide assistance during the postoperative and recovery periods. The patient's vital signs must be stable for the clinician to perform an office D&C. If bleeding has been prolonged or heavy, a hemoglobin or hematocrit should be obtained. The ability to obtain IV access is also important should the need arise to correct hemodynamic instability.

## **ANESTHESIA AND ANALGESIA**

In the outpatient setting, anesthetic and analgesic choice is somewhat limited. For D&C procedures performed in the hospital, the choice of sedation is much wider. No matter which drug regimen is selected, it is important that personnel and equipment for resuscitation be available should anaphylaxis, bleeding, or oversedation

When making anesthetic and analgesic choices for D&C, the clinician should consider the following:

- A paracervical block is useful before placement of a tenaculum onto the cervix and before cervical dilation, unless a general anesthetic is used (see Chapter 173, Paracervical Block).
- Alternatively, a submucosal cervical local block is generally sufficient and easier to perform (see Chapter 149, Loop Electrosurgical Excision Procedure for Treating Cervical Intraepithelial Neoplasia).
- Consider a nonsteroidal anti-inflammatory drug (NSAID) 1 hour before the procedure for office procedures to reduce cramping and decrease uterine bleeding. Diazepam (Valium) 10 mg orally 1 hour before the procedure combined with a maximum-dose NSAID and local lidocaine are generally sufficient to accomplish a D&C.
- IV medication can be used for sedation if needed (see Chapter 2, Procedural Sedation and Analgesia).

# **TECHNIQUE**

- 1. A hematocrit and hemoglobin, Rh, blood type, and screen should be considered if the patient's problem is pregnancy related. Platelet count, prothrombin time, partial thromboplastin time, and fibrin split products may be indicated in some situations. If uncertain of pregnancy status, obtain a pregnancy test
- Start an IV line and administer fluids. Sedate the patient if needed.
- 3. Prophylactic antibiotics, including subacute bacterial endocarditis prophylaxis, are not indicated in routine D&Cs.
- 4. Place the patient in the dorsal lithotomy position.
- Determine the position of the uterine fundus by performing a bimanual examination or using ultrasonographic guidance, if skilled in its use.
- 6. Expose the cervix using a Graves or Auvard speculum and cleanse the vagina, cervix, and posterior fornix with an antiseptic solution (e.g., povidone–iodine, cyproheptadine).
- 7. Put on a sterile gown and gloves.
- 8. Place sterile drapes around the perineum.
- 9. Empty the bladder (if full) with an in-and-out catheter. Alternatively, ask the patient to void just before the procedure.

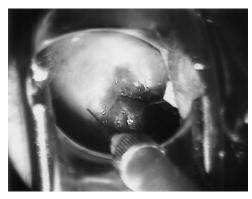

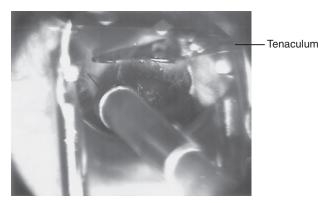

Figure 141-2 Dental anesthetizing gun used for submucosal block.

- 10. Perform a paracervical block (see Chapter 173, Paracervical Block) or submucosal block (Fig. 141-2). This can be omitted if the patient has general anesthesia.
- 11. Grasp the cervix at the 12 o'clock position and elevate it using a tenaculum (Fig. 141-3).
- 12. Perform an endocervical curettage unless the problem is pregnancy related or if one has been performed during a recent evaluation (see Chapter 137, Colposcopic Examination). This is called a *fractional curettage* because the endocervical canal is being evaluated separately from the uterine cavity.
- 13. Use short, firm, in-and-out strokes from the internal os to the external os, curetting in a full 360-degree circle, twice.
- 14. Place the collected tissue on a Telfa pad or common lens paper and send this specimen in a separate formalin container to the pathology laboratory.
- 15. Insert a uterine sound into the os to determine the axis of the cervix and uterine cavity, as well as the depth of the uterus. Greater than 10 cm is abnormal in a premenopausal woman. Most postmenopausal uteri sound less than 8 cm. (For information regarding steps to take when either external or internal os stenosis is encountered, see Chapter 136, Cervical Stenosis and Cervical Dilation).
- 16. Dilate the os to 8 to 12 mm using dilators.
- 17. If using a suction method, insert the largest suction curette that can easily pass through the os and attach the other end to the suction hosing.
- 18. Make sure the suction hosing has a tissue trap.
- 19. Place the curette in the center of the uterus, turn on the suction machine, and close the suction valve on the handle of the curette. A pressure of 60 mm Hg is needed to obtain adequate suction. Use a rotary, slightly in-and-out motion, until an increased resistance to rotation is achieved.

**Figure 141-3** Dental anesthetizing gun used for a paracervical block at fornix. The single-tooth tenaculum has been placed on the anterior tip of the cervix.

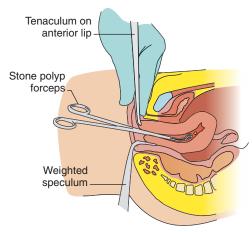

Figure 141-4 Stone polyp forceps used to remove polyp from uterine cavity. (Redrawn from Junnila RD: Dilation and curettage. In Benjamin RB [ed]: Atlas of Outpatient and Office Surgery, 2nd ed. Philadelphia, Lea & Febiger, 1994.)

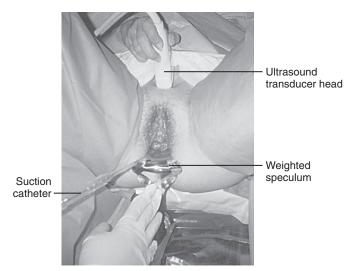

- 20. Curette the entire endometrial lining using a to-and-fro motion. Do not pull the curette past the internal os lest suction be lost. Continue to suction until the entire cavity is sampled and there is no further return of tissue. Turn off the suction and remove the curette.
- 21. Place a Telfa pad or large sheet of lens paper into the posterior vaginal vault.
- 22. Insert a sharp uterine curette and lightly scrape all sides of the uterine cavity. Collect the materials on the Telfa pad or lens paper and send in separate laboratory container.
- 23. Using the Stone forceps, explore the uterine cavity for polyps by systematically opening and closing the forceps while moving across the dome and anterior and posterior walls of the uterus (Fig. 141-4). Remove any tissue grasped with the forceps with gentle pressure or twisting.
- 24. Reinsert the curette and suction out any remaining tissue (optional).

# **Optional Methods**

- The entire procedure can be performed under ultrasonographic guidance (Fig. 141-5).
- Laminaria can be placed in the os the night before the procedure for dilation of the cervix (Chapter 136, Cervical Stenosis and Cervical Dilation).
- A sharp curette alone can be used instead of a suction curette to remove endometrial tissue.
- A curved suction curette is used if the uterus is anteflexed or retroflexed. A straight suction curette is used if the uterus is in midposition.

### **COMPLICATIONS**

- Hemorrhage: This is very rare (<1%) unless the problem is pregnancy related. Most women will have some spotting for a few weeks afterward.</li>
- Infection: This is extremely rare; it is treatable with a broadspectrum antibiotic covering anaerobes.
- Perforated uterus: This is more likely to occur in the presence of
  uterine infection; with a stenotic cervical os (especially in elderly
  postmenopausal women); in cases in which a sharp (as opposed
  to vacuum) curette is used; if there is unrecognized marked anterior or posterior flexion; and in patients who are less than 8 weeks
  postpartum.
  - With lateral perforation, injury to the uterine artery is possible.
  - Anteroposterior perforation is usually not serious if a small curette is used.

**Figure 141-5** Weighted speculum and suction equipment used in dilation and curettage. Ultrasonography is used to guide the physician during the procedure.

- Perforation with a blunt object (usually the uterine sound) is generally uncomplicated.
- Perforation with a sharp object is more significant.
- In most cases, treatment for perforation is simple observation. Perforation should be suspected if the uterine sound or curette passes beyond 9 to 10 cm in the postmenopausal or beyond 12 cm in menstruating women (unless the uterus is actually this large on palpation). If perforation occurs, the procedure should be terminated. Before discharging the patient, the clinician should look for unstable vital signs and significant pelvic pain or bleeding. Some physicians provide antibiotic coverage, although this is not generally done. The patient should report any fever, pelvic pain, or discharge. The risk of perforation is reduced if the D&C is carried out under ultrasonographic guidance.
- Asherman's intrauterine adhesions may cause secondary amenorrhea, infertility, recurrent abortion, or other menstrual irregularities. Postoperative adhesions are more common when the D&C is performed on the puerperal uterus.
- Disease may be missed. In even vigorous D&Cs, studies show only 50% to 60% of the endometrial cavity is actually curetted. The patient and physician must understand that if symptoms persist, a further or repeat diagnostic test may be needed.

# POSTPROCEDURE MANAGEMENT

# Immediately after the Procedure

- After completing the D&C, observe the vital signs for any indication of deleterious effects (i.e., lowered blood pressure, elevated pulse rate, decreased oxygen saturation).
- If continued vaginal bleeding is evident after the procedure, give 10 to 20 U of IV oxytocin (Pitocin) in 1 L of lactated Ringer's solution, and methylergonovine maleate (Methergine) 0.2 mg intramuscularly. This is especially helpful in pregnancy-related procedures.
- If bleeding does not stop, the clinician should inspect for lacerations and use ultrasonography to visualize intrauterine contents to rule out an incomplete evacuation.
- If a significant decrease in blood volume has occurred, it may be necessary to replenish body fluids intravenously using normal saline or lactated Ringer's solution.

 Provide RhoGAM if the patient is Rh negative and the procedure is pregnancy related.

# **Before Discharge**

- The patient should be alert and ambulatory and should have stable vital signs before discharge.
- Consider NSAIDs for pain.
- If the patient is at risk for vaginal infection, consider doxycycline 100 mg twice daily for 7 to 10 days.
- Ergonovine 0.2 mg every 4 hours for 1 to 2 days can be given to decrease bleeding in pregnant patients.

After discharge, consider a postoperative check in 1 to 2 weeks to discuss pathologic tissue findings and assess the patient's well-being.

# POSTPROCEDURE PATIENT EDUCATION

- Instruct the patient to insert nothing in vagina for 2 weeks. This
  includes sexual activity.
- The patient is to call the office if bleeding is greater than one sanitary napkin per hour or if there is fever, purulent discharge, or unrelieved abdominal pain.

#### INTERPRETATION OF RESULTS

# **Normal Findings**

- Proliferative endometrium
- Secretory endometrium
- Atrophic endometrium
- Products of conception

# **Abnormal Findings**

- Endometrial polyp
- Chronic endometritis
- Intrauterine synechiae
- Submucous leiomyoma
- Intramural leiomyoma
- Uterine enlargement
- Vaginal bleeding
- Premenopausal menorrhagia
- Postmenopausal bleeding
- Personal history of cancer uterus
- Endometrial hyperplasia (adenomatous, cystic, glandular)
- Simple endometrial hyperplasia without atypia
- Complex endometrial hyperplasia without atypia
- Complex endometrial hyperplasia with atypia
- Adenocarcinoma in situ
- Endometrial carcinoma (i.e., adenocarcinoma)
- Hydatidiform mole (i.e., trophoblastic disease)
- Malignant hydatidiform mole
- Variations of cervical dysplasia (from endocervical curettage)
  - Cervical intraepithelial neoplasia (CIN) I
  - CIN II
  - CIN III

#### **PATIENT EDUCATION GUIDES**

# HUMAN PAPILLOMAVIRUS DNA TYPING

Gary R. Newkirk

Papanicolaou cervical screening (Pap test) has dramatically reduced the incidence of cervical cancer in developed countries. For nearly 20 years a relationship between human papillomavirus (HPV) infection and cervical cancer has been recognized. HPV is a sexually transmitted DNA virus that causes over 99% of cervical cancer. Of the 120 HPV types, at least 40 are known to infect the anogenital tract causing genital warts or dysplasia (Table 142-1). HPV types have unique biologic potential and often prefer specific sites of infection (hands, feet, and genitals). Among the types that infect a given target tissue, such as the cervix, specific types are more likely to predispose to cancer. HPV types that infect the genitalia can be categorized as high, low, and intermediate risk based on their predilection for causing severe dysplasia.

Other cancers have also been linked to the high-risk HPV viruses, including anorectal, vulvar, vaginal, oropharyngeal, bladder, and nonmelanoma skin cancers, among others. Sophisticated new tests for the detection of HPV hold great promise for improving both the sensitivity and specificity of cervical cancer screening. These new tests have also supported the development of triage mechanisms to help identify women who are at greatest risk for the development of high-grade cervical intraepithelial neoplasia (CIN) or recurrence of disease after treatment for CIN.

Testing for HPV relies on the detection of viral DNA. The only test currently approved by the U.S. Food and Drug Administration (FDA) for the detection of HPV DNA is Hybrid Capture 2 (HC2) system (Digene Corporation, Gaithersburg, MD). This commercially available test uses a liquid hybridization format to detect 13 high-risk HPV types (HR HPV) (genotypes 16, 18, 31, 33, 35, 39, 45, 51, 52, 56, 58, 59, and 68). This test does not distinguish individual HPV types but, rather, identifies "the group." Recently, a standardized polymerase chain reaction (PCR)-based technique (AMPLICOR HPV test, Roche Molecular Systems) for the detection of the 13 HR HPV genotypes has been commercialized. This test is available for clinical diagnostic laboratories, but few data are available on its performance in clinical settings. This discussion will focus on use of the HC2 HPV test. HC2 testing can be performed as both a stand-alone test or combined with Pap testing when a liquid-based Pap test is used (see Chapter 151, Pap Smear and Related Techniques for Cervical Cancer Screening). "Reflex" HPV testing refers to an automatic HPV DNA analysis on a liquid-based Pap test based on the cytologic diagnosis, such as atypical squamous cells of undetermined significance (ASCUS). In this setting, because the same sample aliquot is used, the patient need not return for a separate HPV sample collection examination.

HPV is very common among sexually active women. Nearly 75% of women are infected by age 30. Because most HPV infections are transient and do not progress to severe dysplasia or cancer, the isolated finding of HPV by current technology does not offer sufficient predictive value to replace current cytologic Pap screening. Accordingly, the FDA has not approved currently available HPV

DNA tests as a sole primary method for cervical cancer screening. At present, testing for HPV should be reserved mainly for triage of patients with ASCUS (see Chapter 151, Pap Smear and Related Techniques for Cervical Cancer Screening, Box 151-2, Terminology and Definitions, and Appendix K: Management Guidelines for Abnormal Cervical Cancer Screening Tests and Histologic Findings), screening otherwise healthy women over age 30, and posttreatment or postcolposcopy follow-up. Use of HC2 HPV has clearly been shown to be a useful tool in screening women with ASCUS cytologic features, especially if performed as a "reflex" test after liquid-based Pap smears. HC2 HR HPV detects over 90% of highgrade CIN; a negative test greatly reduces unnecessary colposcopy and treatment. Evidence supports lengthening the screening interval for women over age 30 to 3 years when both Pap and HPV tests are normal. Combined cytologic and HPV DNA testing in women aged 30 years and older is highly sensitive and cost-effective, reducing overall costs by 30%. HPV testing also can be used for postcolposcopy and post-treatment follow-up. Patients with an ASCUS, atypical squamous cells (cannot exclude high-grade squamous intraepithelial lesion [ASC-H]), or LSIL (low-grade squamous intraepithelial lesion) Pap test result who are diagnosed with CIN 1 after colposcopy can be screened either by repeat cytology at 6 and 12 months or with a single HPV test at 12 months. Likewise, women who are treated for CIN 2/3 can be followed by a repeat Pap test with HPV testing at 6 months. If these tests are both negative, the patient can safely return to routine screening. An abnormal HPV or Pap test result necessitates follow-up colposcopy. Of note, HPV testing can be performed on tissue samples (in situ sampling) to help correlate histologic finding with the presence of HPV. Currently, testing for low-risk types of HPV is not recommended. HPV testing is not approved for males.

The American Society for Colposcopy and Cervical Pathology (ASCCP) 2006 Consensus Guidelines for the management of both cytologic and histologic cervical abnormalities are presented as algorithms in Appendix K: Management Guidelines for Abnormal Cervical Cancer Screening Tests and Histologic Findings.

# **ANATOMY**

Cervical testing requires sampling the same area targeted by the Pap smear, namely, the active transformation zone (see Chapter 151, Pap Smear and Related Techniques for Cervical Cancer Screening, Figs. 151-3 and 151-4, and Chapter 137, Colposcopic Examination).

# **INDICATIONS**

- Adjunct to triage of ASCUS cytologic finding
- In combination with Pap testing for women over age 30 years

- For follow-up of women who have colposcopic/histologic findings consistent with CIN 1 without treatment
- For follow-up of women who have had treatment of the cervix for CIN 2/3
- To evaluate the presence of HPV-related abnormal histologic findings (in situ testing)

HPV testing potentially could be useful for evaluation of persistent low-grade cytologic changes in the postmenopausal patient, potential cases of child abuse, and cases of anal-canal disease.

There are no indications at present for testing noncervical lesions for HPV. Some men who have sex with men are now being screened with Pap smears of the anal canal, and HPV testing may become an adjunctive test.

# **CONTRAINDICATIONS**

There are no absolute contraindications. As this procedure is frequently performed at the time of Pap smear, see Chapter 151, Pap Smear and Related Techniques for Cervical Cancer Screening, for contraindications to collection of the sample.

# **EQUIPMENT AND SUPPLIES**

The only test currently approved by the FDA for the detection of HPV DNA is the HC2 system. At the present time the HC2 collection and specimen transport medium (STM) kit is the only HPV DNA testing assay used by clinical reference laboratories. When used in combination with the Pap smear, both the cervical sampling and HPV DNA testing sample can be obtained with the same sampling device. Either a brush type or broom type sampler may be used. ThinPrep is the only liquid-based Pap smear system that is FDA approved for reflex HPV testing. The SurePath collection system is the only other liquid-based Pap system used in the United States.

- Digene HC2 cervical sampling kit with brush, transport tube, and medium is used for stand-alone HPV DNA testing when a liquidbased Pap is not performed.
- Cervical biopsies (or other genital biopsies) are taken with the usual biopsy equipment and placed in the tube with the STM.
- Tissue biopsies from lesions located anywhere on the body can also be placed in standard formalin for transport, although the STM is preferred.
- Pap smear specimens can be collected with either broom or brush devices and placed in the Cytyc PreservCyt solution (Cytyc Corporation, Boxborough, MA).

#### **PROCEDURE**

# **Cervical Sample without Pap Smear Collection**

- 1. The cervix is placed in view as for collecting a Pap specimen (see Chapter 151, Pap Smear and Related Techniques for Cervical Cancer Screening, Fig. 151-3).
- 2. Blot and gently remove excess cervical mucus.
- The special cervical conical brush supplied by the Digene Specimen Collection Kit is inserted into the cervical os until the outer or widest bristles make contact with the cervix or reasonable resistance is encountered for further advancement (Fig. 142-1).
- 4. There is no need to advance the brush farther than 10 to 15 mm.
- 5. Rotate the brush three full turns in a counterclockwise direction.
- 6. Insert the brush into the bottom of the transport tube, snap off the shaft at the scored line, and cap securely.

# Cervical Sample at the Time of Liquid-Based Pap Testing

- 1. The cervix is sampled with the broom or brush (see Chapter 151, Pap Smear and Related Techniques for Cervical Cancer Screening, Fig. 151-4) and rinsed thoroughly in Cytyc PreservCyt solution for use in transporting material for the ThinPrep Pap process.
- The ThinPrep Pap preparation renders a slide for cytologic evaluation. The remaining supernatant must be at least 4 mL and is processed with the Digene HC2 protocol.
- 3. If the Digene sampling kit is used for HPV sampling at the time of a Pap smear (i.e., either in addition to the liquid-based Pap or with conventional Pap testing), the HPV DNA sample should be taken after the Pap sample is taken.
- 4. If HPV DNA sampling is performed at the time of colposcopy, the HPV sample should be collected *before* the use of any applied solutions such as saline, acetic acid, or Monsel's solutions and prior to cervical biopsies.

# **Biopsy Testing for Human Papillomavirus**

 Biopsies may be taken from the cervix, vagina, rectum, vulva, or any other anatomic location and placed in the Digene Specimen Transport Medium. Because there is no other preservative, this sample must be frozen immediately.

**Figure 142-1** The Digene Hybrid Capture 2 (HC2) human papillomavirus (HPV) DNA kit (Qiagen, Inc., Valencia, CA) tests for the 13 most common HPV types known to be associated with high-grade cervical dysplasia and cervical cancer. The kit includes a transport vial with fluid medium and a special conical sampling brush, which is rotated three times in the cervical os and then placed in the transport tube, snapped off, and sealed.

- 2. Biopsy specimens can be tested for in situ hybridization in formalin-preserved and paraffin-prepared histologic blocks.
- Clinicians should check with their reference laboratory regarding the sampling, preparation, and handling of biopsy samples.
   Opinion differs on the ideal manner to handle this tissue for the somewhat rare in situ hybridization protocols.

# **COMPLICATIONS**

None have been reported. Minor spotting as per routine Pap testing is normal.

# POSTPROCEDURE MANAGEMENT

The ASCCP guidelines suggest management based on the results of the HPV testing. These guidelines will be appropriate for most patients but are not a substitute for clinical judgment in the management of cervical dysplasia.

**NOTE:** Operative report, complications, and postprocedure management are identical to Pap smear protocol (see Chapter 151, Pap Smear and Related Techniques for Cervical Cancer Screening).

#### INTERPRETATION OF RESULTS

The HC2 HPV test will be reported as "positive" or "negative." A positive test indicates the presence of one or more of the 13 highrisk HPV viral types in the test. The overwhelmingly most common type causing a positive result is type 16. A negative test indicates either absence of these types or an amount of viral DNA deemed clinically irrelevant. Appendix K, Management Guidelines for Abnormal Cervical Cancer Screening Tests and Histologic Findings, presents the ASCCP 2006 Consensus guideline algorithms, which offer suggested evidence-based management interventions based upon a positive HPV test.

#### **CPT/BILLING CODE**

87621 HPV amplified probe technology interpretation

There is no specific code for collection of the specimen.

# **ENDOMETRIAL BIOPSY**

Beth A. Choby

Endometrial biopsy (EMB) is a safe and cost-effective diagnostic method of evaluating the endometrium. EMB is an office-based procedure most commonly used in perimenopausal and postmenopausal women to investigate abnormal uterine bleeding (AUB) and to rule out endometrial cancer. Endometrial cancer is the most common invasive gynecologic malignancy, and endometrial hyperplasia is sometimes a precursor. EMB may be considered in any woman with risk factors for endometrial hyperplasia or cancer (Box 143-1).

Although EMB is sensitive enough to diagnose hyperplasia or cancer, it is less useful for detecting abnormalities such as endometrial polyps or the changes of endometrial atrophy. The falsenegative rate for EMB is 5% to 15%. Although EMB was the preferred initial procedure for evaluating AUB and had mostly replaced dilation and curettage (D&C), it is now more often used in conjunction with other procedures. Hysteroscopy, transvaginal ultrasonography for endometrial thickness, and sonohysteroscopy are often combined with or done in lieu of EMB (see Chapter 140, Hysteroscopy). Because EMB is cost effective, efficient, and readily available in the outpatient setting, it continues to be an important diagnostic tool.

#### **ANATOMY**

The EMB involves transcervical sampling of the endometrial lining. An endocervical curettage of the cervical canal is performed as part of the EMB.

#### **INDICATIONS**

- Evaluation of premenopausal and postmenopausal AUB
- Work-up of infertility, especially short luteal phase or anovulation
- Assessment of the effects of hormone therapy
- Investigation of atypical glandular cells or endometrial cells on Papanicolaou (Pap) smear in women older than 40 years of age
- Failure to respond to medical treatment of AUB
- Evaluation of abnormal endometrial thickness on transvaginal ultrasonography
- Surveillance in women previously diagnosed with endometrial hyperplasia
- AUB in women with risk factors for endometrial cancer (see Box 143-1)
- Women with an intact uterus receiving unopposed estrogen therapy
- Evaluation for endometrial carcinoma or precancerous changes
- Identification of causes of dysfunctional uterine bleeding
- Evaluation of uterine enlargement in conjunction with ultrasonography
- Screening in hereditary nonpolyposis colon cancer syndrome (HNPCC). The lifetime risk of endometrial cancer in women with HNPCC ranges between 32% and 60%. Annual or biennial endometrial biopsy or transvaginal ultrasonography is recom-

mended in women with HNPCC beginning at 30 to 35 years of age. Recommendations are based on expert opinion because the effectiveness of gynecologic surveillance is not definitive. Diagnosis of HNPCC requires histologically confirmed colorectal cancer in three relatives, at least one of whom must be a first-degree relative. Two successive generations must be affected and one case has to be diagnosed before 50 years of age. Screening is appropriate in known carriers of this autosomal dominant gene or in cases where there is strong suspicion of HNPCC.

#### **CONTRAINDICATIONS**

#### **Absolute**

- Pregnancy
- Bleeding diathesis/coagulopathy

#### **Relative**

- Use of anticoagulant therapy
- Active vaginal, cervical, uterine, or pelvic infection
- Cervical stenosis
- Morbid obesity
- Significant pelvic relaxation with uterine prolapse

#### **EQUIPMENT**

A variety of instruments are available for EMB. The more popular methods are described for comparison. Equipment common to all methods is listed here; additional items required with specific aspirators are listed in the aspirator descriptions.

- Large Graves vaginal speculum
- Povidone-iodine solution in nonallergic patients
- Cotton balls
- Ring forceps
- Uterine sound
- Single-tooth tenaculum
- Endocervical curette without basket (e.g., Kevorkian curette)
- Buffered formalin specimen containers with patient identification labels (two)\*
- Endometrial sampler (special equipment requirements by method)
  - Disposable flexible plastic endometrial aspirator (e.g., Pipelle, Pipet Curet, Endocell)
  - Scissors
  - Reusable stainless steel curette (Novak or Randall)
  - 20-mL syringe
  - Disposable endometrial aspirators with syringe suction (Cannula Curette, Uterine Explora, Explora II)

<sup>\*</sup>The Tao Brush uses CytoRich Red solution instead of buffered formalin for specimen preservation.

# Box 143-1. Risk Factors for Endometrial Hyperplasia and Cancer

Age >50 years

Atypical endometrial hyperplasia

Chronic anovulation

Diabetes

Infertility

Menopause after 55 years of age

Nulliparity Chronic anovulation

Obesity\*

Tamoxifen

Unopposed estrogen therapy

\*21 to 50 pounds overweight carries relative risk three times less than >50 pounds overweight.

- A Tis-U-Trap endometrial curette or a Vabra aspirator (disposable)
- External suction pump
- Brush sampler (Tao Brush)

Cervical dilators should be kept available (see Chapter 136, Cervical Stenosis and Cervical Dilation).

# **PRECAUTIONS**

- The previous Pap smear should be reviewed before the procedure.
   If no recent smear report is available and it is indicated, obtain one before proceeding with the endometrial biopsy (EMB).
- A bimanual examination identifies extreme uterine anteversion or retroflexion. There is an increased risk of uterine perforation when sounding the uterus or collecting the EMB if significant angulation is present between the cervical neck and uterus.
- The use of small cervical dilators is often necessary in women found to have cervical stenosis, so they should be available. Methods for managing cervical stenosis are described in Chapter 136, Cervical Stenosis and Cervical Dilation.

# PREPROCEDURE PATIENT EDUCATION AND FORMS

- Obtain a thorough history and review pertinent clinical records (see encounter form online at www.expertconsult.com). Explain to the patient the indications for the procedure, the process itself, side effects, and potential complications so that she may provide informed consent. See the sample patient education handout and the sample patient consent for "Endometrial Biopsy" available online at www.expertconsult.com.
- Nonsteroidal anti-inflammatory drugs (NSAIDs) effectively decrease uterine cramping during EMB. Patients can be instructed to take 600 to 800 mg of ibuprofen orally 30 to 60 minutes before the procedure unless they are allergic to aspirin or NSAIDs. Other NSAIDs have similar efficacy.
- In extremely anxious patients, premedication with an oral anxiolytic such as 10 mg of diazepam (Valium) 1 hour before the EMB is an option. Patients receiving these medications should be counseled to bring a family member to drive them home.
- The American Heart Association does not recommend antibiotic prophylaxis against bacterial endocarditis before EMB because the procedure is unlikely to cause bacteremia. No current studies specifically stratify this risk.
- Postmenopausal women can be scheduled for EMB at any time, although significant bleeding episodes are best avoided to optimize sample size.

 EMB in reproductive-age women is best performed on day 22 or 23 after the first day of the last menstrual period. The presence of secretory glands confirms that ovulation has occurred. Avoid EMB during menses because stromal breakdown can be misinterpreted as cell fragmentation and hemorrhage due to malignancy.

#### **PROCEDURE**

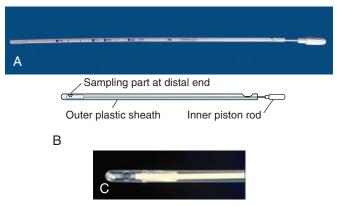

The initial steps for endometrial biopsy are similar for the various methods. These are listed first (steps 1 through 8) and followed by descriptions of individual endometrial aspirators and specific instructions for their use. Confirm that the patient is not pregnant, if appropriate, before beginning the procedure.

- 1. The patient is placed in stirrups in dorsal lithotomy position (after the Pap smear is obtained, if indicated) and a *bimanual examination* is performed to determine the size and position of the uterus. The provider wears nonsterile gloves for this portion of the procedure.
- 2. *Insert a large Graves speculum* vaginally. Visualize the cervix and remove any mucus or debris.
- 3. Change into sterile gloves.
- 4. Prepare the cervix and vagina with povidone–iodine–soaked cotton balls using the ring forceps.
- 5. Perform an endocervical curettage in cases where neoplasm is suspected (see Chapter 137, Colposcopic Examination). Insert a Kevorkian curette without basket or a disposable curette into the endocervical canal. Manipulate the curette 360 degrees circumferentially around the entire canal, scraping in and out for two full rotations. Warn the patient about cramping. Collect all of the available material. Use ring forceps to collect any blood or secretions draining from the os. Place all the material on lens paper and then place it in formalin.
- 6. If insertion of the curette is difficult, use a single-tooth tenaculum to grasp the cervix at 12 o'clock. Traction on the tenaculum straightens the cervical neck and allows for easier endocervical curettage. Avoid grasping the 3 and 9 o'clock positions because of the presence of arteries at these points. Topical benzocaine gel (20%) or benzocaine spray (Hurricaine) may be applied to the tenaculum site to decrease pain. If used, the anesthetic needs to be in place several minutes before it has an effect. A submucosal injection of lidocaine works well (see explanation in Chapter 149, Loop Electrosurgical Excision Procedure for Treating Cervical Intraepithelial Neoplasia).
- 7. Once a gritty sensation is noted, remove the curette. Collect all tissue obtained and place it in formalin.
- 8. Proceed with EMB using one of the following techniques. With all endometrial biopsy techniques, insert the sterile sampling device through the cervical os without touching the vulva or vaginal walls. Do not touch or contaminate the part of the sampler that is placed into the uterus. Sterile gloves and speculum are not necessary if a "no-touch" technique is used.

# Plastic Endometrial Aspirators (Pipelle or Endocell Endometrial Aspirator)

Disposable flexible endometrial sampling devices are the most popular method for EMB (Fig. 143-1A and B). The device is made of a clear, flexible polypropylene tube with an inner plunger. This functions as a piston and creates negative pressure when retracted quickly. A 2.4-mm distal side port allows for tissue sampling. The stiffer-tipped aspirators are more useful when cervical stenosis is present. More flexible types may be "stiffened" by placing them in a freezer for 10 to 15 minutes.

The Pipelle samples 5% to 15% of the endometrial surface. Several types are calibrated and can be used to sound the uterus (6.5 to 10 cm is normal). Seventy-seven to 99% of specimens obtained using the Pipelle are adequate for histopathologic diagnosis.

**Figure 143-1** A, Pipelle endometrial sampler. B, Depiction of Pipelle sheath and piston. C, The opening at the end of the Pipelle. (Courtesy of CooperSurgical, Inc., Trumbull, Conn, with permission.)

The procedure for flexible endometrial aspirators follows, continued from previous steps 1 through 8.

9. Sound the uterus using either a calibrated flexible aspirator with the piston fully inserted or a metal sound (when using an uncalibrated product). Document the depth of the endometrial cavity (usually 6.5 to 10 cm). If the sound cannot be inserted, use a tenaculum to grasp the cervix at 12 o'clock. Outward traction straightens the cervical neck and allows the sound to pass through the cervical os. If the sound still will not pass, cervical dilation may be necessary (see Chapter 136, Cervical Stenosis and Cervical Dilation).

- 10. *Introduce the aspirator*, with internal piston fully inserted, into the endocervix. Pass it through the cervix and into the uterine cavity. Stop once the fundus is reached or resistance is encountered (Fig. 143-2A).
- 11. Stabilize the sheath with one hand while the *piston is drawn back* with the other hand. Negative pressure builds up in the lumen of the tube (Fig. 143-2B).
- 12. Rotate the sheath 360 degrees between the thumb and index finger. At the same time, withdraw the aspirator going from the fundus to the internal os. Most of the endometrial cavity can be sampled with a minimum of four complete in-and-out circumferential passes. As the aspirator completes a helical arc against the uterine walls, negative pressure within the sheath draws the sheared-off endometrial tissue through the distal port and into the lumen. The aspirator must be kept within the cervix or suction is lost (Fig. 143-2C).
- 13. Withdraw the entire device from the uterus, with the piston pulled back the full distance. Avoid contaminating the tip. Do not push the piston back into the sheath before removal because the tissue sample will be lost.
- 14. Expel the sample into formalin by advancing the piston into the sheath (Fig. 143-2D–F). If insufficient tissue is obtained or if the aspirator fills with blood or other material before four complete passes have been made, a second insertion may be attempted using the same catheter as long as it has not touched the formalin or vaginal sidewalls. The manufacturers often recommend that the tip of the catheter be cut off using scissors before the sample is expelled into formalin, although this is unnecessary. Additional sampling would then require an additional unused aspirator.
- 15. Remove the speculum from the vagina.

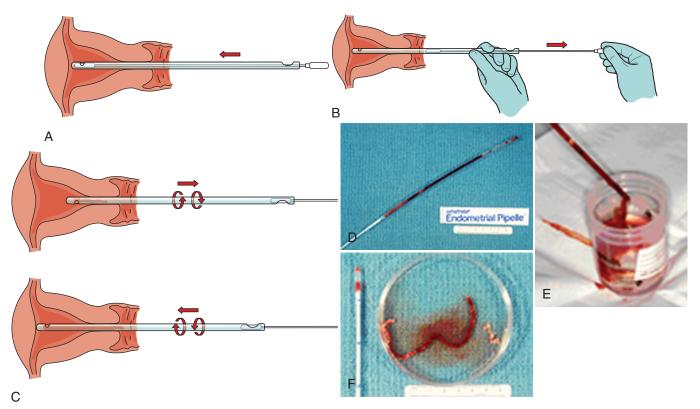

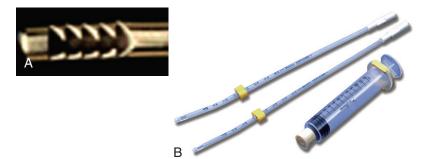

Figure 143-2 A, With the piston fully advanced in the sheath, insert the aspirator transcervically into the endometrial cavity. B, Hold the outer sheath with one hand while simultaneously pulling back the piston to create negative pressure. C, Roll the sheath between the fingers while simultaneously moving the sheath in and out from the fundus to the internal os. Complete a minimum of four passes. D, Appearance of tissue in the sampler. E, Expressing the tissue into the formalin bottle. F, The sample as it appears in the formalin container.

**Figure 143-3 A,** Close-up of the end of the Novak stainless steel curette. **B,** Uterine Explora and Explora II endometrial aspirators. (Courtesy of CooperSurgical, Inc., Trumbull, Conn, with permission.)

# Reusable Stainless Steel Curette (Novak or Randall) and Disposable Endometrial Aspirators with Syringe Suction (Cannula Curette, Uterine Explora, Explora II)

The Novak curette is made of *stainless steel* and has been available for over 50 years (Fig. 143-3A). The cannula is rigid and is attached to a 10- to 20-mL disposable plastic syringe. When the syringe plunger is pulled, the negative pressure generated draws endometrial tissue into the cannula. Both the Novak and Randall curettes are reusable after sterilization. A disadvantage of this method is that patients complain of greater pain than with flexible plastic aspirators.

Several disposable methods allow easier use of suction by connecting a locking syringe to the end of the plastic aspirator. The Cannula Curette, Uterine Explora, and Explora II combine the benefits of a rigid cannula with disposability. Both Explora models are nylon with a sharp Randall-type cutting edge (Fig. 143-3B and C). The Explora has one distal port, whereas the Explora II has two distal ports on opposing sides of the aspirator. Tissue is obtained with suction using a scraping and peeling action. In women with large endocervical canals, the Cannula Curette may be a better option (Fig. 143-4). It comes in sizes ranging from 3 to 7 mm, whereas the Explora and Explora II are available only in 3- and 4-mm sizes. When AUB is present, the larger-diameter Cannula Curette is less likely to clog than the smaller curettes. Sensitivity and specificity of these types of endometrial samplers are similar to those for the flexible plastic endometrial aspirators.

After completing previous steps 1 through 8, the procedure for the reusable stainless steel curette (Novak or Randall) and disposable endometrial aspirators with syringe suction (Cannula Curette, Uterine Explora, Explora II) is as follows:

9. Apply a tenaculum to the anterior or posterior tip of the cervix, depending on the direction of flexion of the uterus. Grasp the cervix with the tenaculum teeth in the horizontal position. Grasping the cervix at the 3 or 9 o'clock position with the tenaculum in the vertical plane decreases the diameter of the external os. Local anesthesia (2 mL 2% lidocaine solution or

**Figure 143-4 Cannula curette endometrial aspirator.** (Courtesy of CooperSurgical, Inc., Trumbull, Conn, with permission.)

- spray) where the tenaculum teeth are applied decreases patient discomfort (optional).
- 10. Insert a uterine sound into the cervix while applying gentle traction to the tenaculum. Halt when the fundus is reached and note the insertion measurement in centimeters. Remove the sound from the patient. If stenosis is present, cervical dilation may be necessary (see Chapter 136, Cervical Stenosis and Cervical Dilation).
- 11. Gently *insert the curette* into the endometrial cavity while applying traction with the tenaculum. Stop insertion once the curette is at the depth that was sounded.
- 12. Before attaching the curette, *draw up 1 to 2 cm of air into the syringe*. This will be used to evacuate the curette when the procedure is completed.
- 13. Attach a 20-mL syringe to the curette hub. Pull the syringe back to the 10- to 15-mL mark to create suction. The Explora models recommend pulling the syringe back to 1 or 2 mL to avoid discomfort.
- 14. Apply pressure against the uterine sidewalls and *perform four to six single-strip curettages*. Sample from the fundus to the lower uterine segment and obtain at least one sample from each quadrant. More sampling can be done if the patient is tolerating the procedure well.
- 15. Release the pressure on the syringe, withdraw the curette from the uterus, and express the sample into the formalin bottle by pushing the plunger of the syringe toward the curette. Label the formalin bottle.
- 16. Remove the speculum from the vagina.

#### Tis-U-Trap and Vabra Aspirator

The sterile and disposable Tis-U-Trap is a clear *plastic* tissue collection chamber (Fig. 143-5). It comes with a funnel, two sealing caps, a resealable bag, and either a flat or cone-shaped tissue trap. The Tis-U-Trap is used with one of several types of endometrial curettes. The trap is attached to an external suction source such as a pump

**Figure 143-5** Tis-U-Trap plastic disposable aspirator, including flat and cone-shaped collection chamber, sound, and endometrial curettes. (Courtesy of CooperSurgical, Inc., Trumbull, Conn, with permission.)

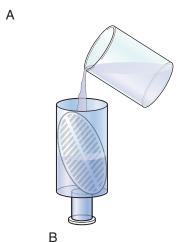

or wall suction. Endometrial tissue is aspirated directly into the collection chamber, eliminating the need to transfer the tissue sample into another container. The design of the collection chamber permits easy visualization of the tissue collected and simplifies routine tissue handling for pathology.

The Vabra aspirator uses a 4-mm disposable curette or 2- to 3-mm stainless steel curette with an external vacuum pump. The vacuum pump is noisy, and this method is less commonly used than those listed previously. Tissue collected is gathered from a trap and placed in formalin. An advantage of the Vabra aspirator is the large tissue sample obtained, although the larger, rigid cannula is more uncomfortable for the patient.

After completing previous steps 1 through 8, follow these steps for using the Tis-U-Trap or Vabra aspirator:

- 9. Apply a tenaculum to the anterior or posterior lip of the cervix.
- 10. Using a metal sound, carefully measure the depth of the endometrial cavity. Measurements usually range between 6.5 and 10 cm. If stenosis is present, cervical dilation may be necessary (see Chapter 136, Cervical Stenosis and Cervical Dilation).
- 11. Attach the device to the external suction pump.
- 12. *Insert the curette* through the cervical os and gently advance until the fundus is reached. The depth should coincide with the uterine sound measurement.
- 13. Activate the pump to 55 cm  $H_2O$ .
- 14. *Initiate suction* by covering the suction hole with a finger (Fig. 143-6A).
- 15. Carefully *curette the entire endometrium* using a circumferential in-and-out movement. Keep the curette within the uterine cavity. The tissue passes through the curette and into the trap, where it collects on the grid.
- 16. When sufficient tissue accumulates in the trap, *halt suction* and then remove the curette from the uterus.

**Figure 143-6 A**, Initiate suction by covering the hole on the curette. **B**, Remove the curette from the trap and cap the outlet. Pour formalin into the trap to cover all tissue and then seal.

**Figure 143-7** Tao Brush. **A,** Endometrial sampler with sheath. **B,** Brush inserted in the endometrial cavity with sheath retracted to allow for sampling. (Courtesy of Cook Women's Health, Spencer, Ind, with permission.)

- 17. Turn the suction pump off and disconnect the curette from the trap.
- 18. Add formalin to the trap and ensure that all tissue is exposed. Cap and label the trap for submission to pathology (Fig. 143-6B).
- 19. Remove the speculum from the vagina.

# Tao Brush

The Tao Brush sampler consists of a tube with a distal brush (Fig. 143-7A). The brush is covered by a 26-cm, 9.0-Fr vinyl sheath. By keeping the brush covered during insertion, the sheath allows for sampling of endometrial cells only, without contamination from the vagina or cervix, because the brush is uncovered only once it is in the uterine cavity. The brush obtains an adequate sampling from the entire endometrium. It is supplied in a sterile package and intended for one-time use only. The Tao Brush may be used alone or before or after use of a plastic aspirator.

After following previous steps 1 through 8, the Tao Brush procedure is as follows:

- 9. Sound the uterus (up to 10 cm is normal). If stenosis is present, cervical dilation may be necessary (see Chapter 136, Cervical Stenosis and Cervical Dilation).
- Insert the Tao Brush with the outer sheath covering the brush. Gently advance it until the fundus is reached, based on the initial sounding depth.
- 11. Slide back the outer sheath to expose the plastic bristles and rotate 360 degrees 10 times against the uterine walls (Fig. 143-7B).
- 12. Slide the sheath back in to cover the brush and then remove the Tao Brush and speculum.
- 13. Place the brush into the supplied CytoRich Red. Pull the sheath back and forth 10 times to dislodge the endometrial tissue. CytoRich Red hemolyzes blood and allows the pathologist to prepare a "thin-layer" sample (liquid-based cytology).

# SAMPLE OPERATIVE REPORT

See the sample encounter form online at www.expertconsult.com.

#### **COMMON ERRORS**

- Inability to develop suction with a Pipelle or Novak/Randall-type endometrial aspirator. If the endocervical canal is large, change to a larger-diameter cannula and reattempt aspiration.
- Loss of suction during the biopsy. If the distal port of the Pipelle
  or syringe suction aspirator is pulled too far outside the
  endocervix, suction is lost as air is pulled in. Keep the aspirator
  within the uterine cavity and endocervix until the sample is
  obtained.
- Use of a small-diameter cannula in the setting of significant uterine bleeding. Large clots clog the cannula and make obtaining an adequate sample (rather than just blood) challenging. Switch to a larger-diameter cannula and reattempt aspiration.

#### **COMPLICATIONS**

- Uterine perforation occurs in 0.1% to 1.3% of EMBs. Perforation most often occurs with the use of rigid devices, while sounding the uterus, or when the cervix is stenotic. If the uterine sound passes more than 12 cm in a uterus that does seem that large on palpation, perforation is suspected. Stop the procedure and withdraw all instruments. Observe the patient closely for bleeding. No other intervention is indicated unless symptoms develop. Patients may be discharged home with close follow-up if bleeding is minimal and vital signs are stable after 30 minutes of observation. Precautions regarding infection and bleeding should be discussed before release. Repeat biopsy can be attempted in 6 to 8 weeks.
- Excessive uterine bleeding is possible, especially in patients with undiagnosed coagulation disorders or perforation.
- Missed pathology is possible because only a small area of the endometrium is sampled. Although the sensitivity of EMB is estimated to be high as 96%, it may miss up to 18% of focal lesions. Fibroids and polyps will also not be identified.
- A vasovagal response occurs in an estimated 10% of patients after EMB.
- Although most women experience cramping during the endocervical curettage, pain after the procedure is usually minimal. Pain lasting longer than 24 hours should be reported to the provider.
- Bacteremia, septicemia, and endocarditis have been reported after EMB, although they are exceedingly rare. The patient should report any fever or foul discharge.

#### POSTPROCEDURE MANAGEMENT

- Patients should remain semirecumbent for 10 minutes after the EMB has been taken. Assess for vasovagal reaction.
- Painful uterine cramps (if present) usually subside rapidly or are relieved with NSAIDs.
- Patients with minimal cramping and bleeding may be discharged home.
- Although a follow-up visit is usually not necessary, it may be needed to discuss pathology findings. If AUB persists, further evaluation with a repeat EMB, D&C, hysteroscopy, or pelvic ultrasonography is indicated.

#### POSTPROCEDURE PATIENT EDUCATION

Bleeding and cramping usually resolve within 24 to 48 hours. Fever, cramping lasting longer than 48 hours, or bleeding heavier than a normal period should be reported. NSAIDs can be used for pain or

cramping. Sexual relations may be resumed after bleeding has stopped.

#### INTERPRETATION OF RESULTS

- 1. When submitting an endometrial biopsy, conveying adequate clinical history to the pathologist is essential. The patient's age, clinical indication for biopsy, menopausal status, and date/length of last menstrual period in premenopausal women are important. Exogenous hormones, hormonal contraceptives, and drugs like tamoxifen can alter the morphology of the endometrium and cause false-positive or false-negative results (Fig. 143-8).
- 2. Biopsy interpretation is based on the status of the functionalis layer located in the upper two thirds of the endometrium. The basalis layer usually shows minimal change. Atrophic, denuded, or scarred endometrium may not yield sufficient tissue for diagnosis. *Inadequate samples* are possible in biopsies immediately after menses, with hypoestrogenism, with prolonged bleeding, or with intrauterine adhesions/synechiae. Menopausal status has a greater effect on specimen adequacy than the type of instrument used (Box 143-2).
- 3. The classification of endometrial hyperplasia is made according to guidelines from either the International Society of Gynecological Pathologists or the World Health Organization (Box 143-3). Endometrial hyperplasia covers a spectrum of alterations in the stroma and glands of the endometrium. Changes range from hyperplasia to atypical hyperplasia to carcinoma. Both hyperplasia and atypical hyperplasia are further categorized as either simple or complex:
  - Simple hyperplasia describes an increased glandular-to-stromal ratio without evidence of glandular crowding or cellular atypia. Cystic hyperplasia is an older term that is no longer used. There is no clinical significance to this finding and no treatment is needed.
  - In complex hyperplasia, infolding and budding of the glands is noted. Glands are crowded in comparison to simple hyperplasia, but no atypia is noted. The older term adenomatous hyperplasia is no longer in use.
  - In atypical hyperplasia, cytologic atypia is divided into simple or complex categories depending on the glandular architecture. Large nuclei of varying shape and size, increased nuclearto-cytoplasm ratio, and prominent nucleoli are commonly described.
- 4. Endometrial hyperplasia without cytologic atypia is usually managed with progestins; 20 mg medroxyprogesterone acetate given twice daily is prescribed for 3 to 6 months. EMB is repeated after therapy, and complete reversal of lesions is often noted. If hyperplasia without atypia is again confirmed, a repeat course of progestin with follow-up EMB or hysteroscopy can be performed. Some patients may opt for a hysterectomy at this point.
- Hyperplasia with cytologic atypia is best managed with a hysterectomy because of the risk of progression to adenocarcinoma. Approximately 10% of women with postmenopausal bleeding have endometrial cancer.
- 6. Histology determines management. Severity of endometrial hyperplasia and the probability of cancer *cannot* be determined by the amount of bleeding, at what point during the menstrual cycle the bleeding occurs, the gross appearance of the sample, or the tissue volume obtained by biopsy. Histopathology must be determined. Transvaginal endometrial thickness measurement is never a substitute for histologic tissue assessment in symptomatic women.

### Pregnancy Related

Retained products of conception

Decidua (consider an ectopic or missed abortion)

#### Infectious Etiology

Endometritis, treat as indicated

#### Abnormal

Rarely, endometrial polyp Simple (cystic) hyperplasia

 Risk for progression to cancer extremely small; little need for follow-up unless symptoms present.

Complex (adenomatous) hyperplasia

- Low but some risk for progression to cancer.
- Treat with progestational agents and follow up with tissue sampling in 6 months.

Atypical hyperplasia (simple and complex)

- Significant risk for progression to cancer.
- Consider hysterectomy because of significant risk of progression to invasion and need for long-term followup to detect progression. If childbearing not complete, treat with progestational agents and follow with frequent biopsies. Referral and consultation should be strongly considered.

#### Adenocarcinoma

Referral indicated for appropriate work-up and

If the endocervical curettage is positive for dysplasia, a conization is indicated. If symptoms persist in spite of treatment, regardless of biopsy results, further evaluation is indicated.

# HYSTEROSALPINGOGRAPHY AND SONOHYSTEROGRAPHY

Steven Fettinger • Linda Fanelli

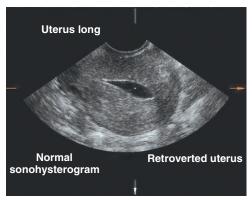

Hysterosalpingography (HSG) is a radiologic examination of the female genital tract. It allows for the evaluation of the cervical canal, endometrial cavity, tubal lumen, and the periadnexal area. The basic infertility work-up includes HSG, although some physicians feel that it has been superseded by laparoscopy with hysteroscopy. However, it remains an integral part of many other diagnostic work-ups. HSG is a relatively easy procedure, requires no anesthesia, and has a low complication risk. Its use as a therapeutic procedure for enhancing fertility is promoted by some clinicians. The addition of selective cannulation of the cornual ostia has eliminated many false positives (or blockage) and opened new therapeutic options. These additions, however, require special training and currently limit the use of HSG in this manner to an infertility specialist or an interventional radiologist. The radiation exposure is usually minimal, in the 50 to 500 mrem ranges.

Saline infusion sonohysterography (SIS) is a technique for visualization of the reproductive tract using ultrasound and the injection of sterile normal saline as an ultrasonic contrast medium. The ease of this procedure and the availability of ultrasound in the office have been responsible for its rapid growth. The discomfort involved is usually less than that of HSG, but the complications and contraindications are similar. A vaginal probe ultrasound and catheterinjected normal saline (or ultrasonic contrast medium, not yet FDA [Food and Drug Administration] approved for gynecology) are used for imaging of the anatomy. The procedure itself is simple, but the expertise and experience needed for interpretation require specialized training. The decreased accuracy in visualizing the fallopian tubes limits its use for this purpose. However, these limitations are compensated for by the ability to identify endometrial pathologic changes and to define uterine anomalies.

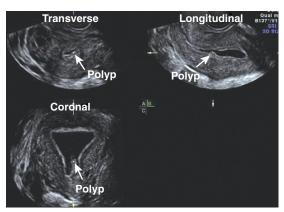

Many clinicians start their work-up of a patient with abnormal uterine bleeding with a transvaginal ultrasonic measurement of the thickness of the endometrial stripe to rule out endometrial cancer. Ultrasonic evaluation of the endometrial stripe thickness in the work-up of abnormal uterine bleeding has been enhanced greatly by using SIS in combination. Endometrial thickness of 5 mm or less is thought to represent dysfunctional uterine bleeding. However, ethnic variations exist and cancer has been found in Japanese women with stripes only 3 to 4 mm thick. SIS is performed in patients with double layer endometrium thicker than 5 mm. Single layer endometrium of 3 mm or less, with no focal abnormalities on SIS, is also treated as dysfunctional uterine bleeding (Fig. 144-1). Symmetrical thickening of the single layer endometrium greater than 3 mm, with no focal lesions, is evaluated by an office endometrial biopsy. A newly available SIS catheter allows an immediate endometrial biopsy, if indicated, through the same catheter. Endometrium with focal lesions or asymmetry requires hysteroscopy and directed biopsy (Fig. 144-2). Hormone replacement and the use of tamoxifen also affect uterine lining, requiring the use of different discrimination thicknesses.

#### **INDICATIONS**

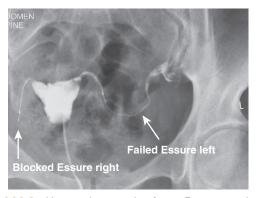

- Infertility (uterine)
  - Endometrial adhesions (Asherman's syndrome)
  - Submucosal polyps
  - Pedunculated endometrial leiomyomas
  - Uterine anomalies
  - Diethylstilbestrol (DES): T-shaped uterus
- Infertility (tubal)
  - Assessment of tubal patency
  - Salpingitis isthmica nodosa
  - Periadnexal adhesive disease
  - Tubal cannulation procedures
  - Follow-up after a medically or a surgically treated ectopic pregnancy
- Habitual abortions
  - Asherman's syndrome
  - Uterine anomaly
  - DES changes
  - Leiomyomas
- Cervical incompetency (controversial indication)
- Preoperative and postoperative evaluation
- Tubal reanastomosis/reimplantation, tuboplasty
- Confirmation of tubal occlusion after Essure contraceptive coil insertion (Fig. 144-3)
- Uterine septal resection, metroplasty
- Myomectomy
- Localization of lost intrauterine contraceptive device (IUD); ultrasound alone is the procedure of choice
- Abnormal uterine bleeding (SIS)

# **CONTRAINDICATIONS**

#### **Absolute**

- Active salpingitis
- Pregnancy

#### **Relative**

- Recent dilation and curettage
- Allergy to contrast medium
- Untreated sexually transmitted disease (STD)

# **EQUIPMENT AND SUPPLIES**

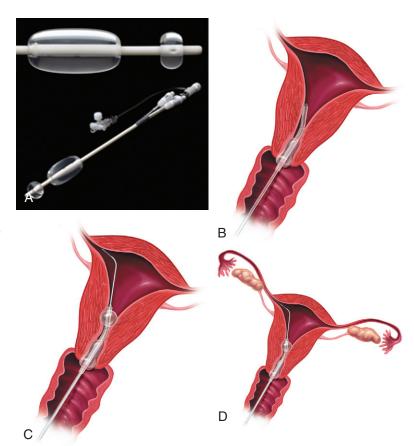

Cannulas

Many types of HSG cannulation devices are available. The choice of catheters used may depend on procedure indication and physician preference. Three general types are in common use, with multiple modifications (the flexible balloon cannulas are also used for SIS):

- 1. Olive-tipped cannulas. A small cannula traverses the cervical canal, and an olive- or cone-shaped seat is held against the cervix os to seal it (Fig. 144-4).
- 2. Suction cannulas. A small cannula is held in place and sealed by a suction cup on the ectocervix.
- 3. Balloon cannulas. One or two balloons are used to fix and seal the cervix. A primary intrauterine balloon is pulled down against the internal cervical os by a second balloon, a springloaded platform, or manual traction. The balloon catheters (including pediatric Foley catheters) obscure the lower uterine anatomy; however, the balloon can be deflated near the end of the procedure, and additional contrast dye can be injected to evaluate this area (Figs. 144-5 and 144-6).

**Figure 144-7** Selective cannulation of the fallopian tube. **A,** Preassembled Mencini double balloon catheter. **B,** Balloon cervical cannula (BCC) in uterus. **C,** Selective salpingography catheter (SSC) passes through BCC. **D,** Inner catheter through SSC. (Courtesy of Cook Ob/Gyn, Spencer, IN.)

Special selective cannulation catheterization systems are available from Cook Medical (see the "Suppliers" section). These catheters are used to selectively cannulate and evaluate a fallopian tube in special circumstances (e.g., unilateral or bilateral nonvisualization, salpingitis isthmica nodosa, or prior ectopic pregnancy). They may also be used therapeutically in some patients to open a blockage in the proximal tubes (Fig. 144-7).

SIS catheters with and without cervical sealing balloons and sponges are used for these procedures. In addition, an infusion/endometrial biopsy catheter makes it possible to biopsy at the same time (Box 144-1).

Oil-based (Lipiodal or Ethiodol)

Nonionic water-soluble: Hypaque-60 (Winthrop-Breon Pharmaceutical)

SHSG contrast

Normal saline

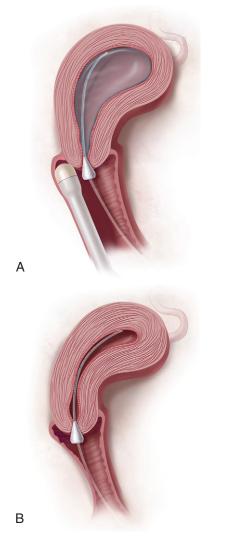

Echovist (Schering-Berlin Pharmaceutical)

Albunex (Mallinckrodt Pharmaceutical)

Most centers currently use water-soluble dye. There has been continued controversy regarding the use of water-soluble versus oilbased media (Table 144-1). The question of ionic or nonionic water-soluble dye depends on the preference of the radiologist. The majority of centers are using the less expensive ionic dyes, except

**Figure 144-8** Goldstein sonohysterography catheter. (Courtesy of Cook Medical, Bloomington, IN.)

in patients with a history of an iodine allergy. Preprocedural administration of antihistamines and steroids may reduce this risk in allergic patients. Alternatively, gadolinium radiologic contrast agent can be used in iodine-allergic patients without renal failure.

 Prep tray, including 4 × 4 inch gauze pads, ring forceps, povidoneiodine solution, medicine cups, lubricating jelly, and a plastic speculum (prep trays with catheters included are available)

- Vaginal speculum
  - One-armed Graves speculum (removable after placement of cannula)
  - Plastic nonradiopaque (disposable)
- Tenaculum (if needed to fixate cervix for cannula placement)
- Syringe, 10 or 20 mL

#### **PRECAUTIONS**

- HSG should be performed in the preovulatory phase of the menstrual cycle to avoid exposing an embryo to radiation and to decrease the risk of infection (infection rates are higher if the procedure is performed during the secretory phase). SIS is performed as soon as possible after menstruation ends to minimize endometrial growth/thickness. HSG/SIS during the preovulatory phase will also avoid the possibility of dislodging a preimplantation conception, and thereby theoretically prevent an ectopic pregnancy.
- Patients with a history of salpingitis require negative cultures for sexually transmitted disease and a nontender preprocedure pelvic examination. Some practitioners require a normal sedimentation rate as well.
- Patients with a history of pelvic inflammatory disease or prior tuboplasty should be treated with prophylactic antibiotics. One option shown to be effective is doxycycline 200 mg the morning of the procedure and 100 mg twice a day for 5 days following the procedure. Antibiotic prophylaxis is controversial for patients without a history of pelvic inflammatory disease or prior tuboplasty. Many physicians now use prophylaxis with all patients undergoing HSG, despite the lack of evidence of its usefulness in low-risk patients. The use of prophylactic antibiotics for SIS is even less well studied, but they are used by some sonographers.

Medium     Advantages     Disadvantages       Water-soluble     Rapidly absorbed Less need for delayed films     No enhancement of fertility       Improved visualization of details	TABLE 144-1 Selection of Contrast Medium			
soluble Less need for delayed films Improved visualization	Medium	Advantages	Disadvantages	
Cil-based Possible fertility Delayed films may be needed Granuloma formation possible Embolism if extravasation occurs	soluble	Less need for delayed films Improved visualization of details Extravasation tolerated Possible fertility	Delayed films may be needed Granuloma formation possible	

 Preoperative medications may include a nonsteroidal antiinflammatory agent, such as ibuprofen 600 mg, given 1 to 2 hours preoperatively, to decrease pain and cramping. The effectiveness of this premedication, however, is limited at best. Diazepam 10 to 20 mg 1 to 2 hours preoperatively may be given for extreme apprehension.

#### PREPROCEDURE PATIENT EDUCATION

- Discuss the procedure, the typical findings, and alternatives to, risks of, and possible complications of the procedure with the patient (obtain informed consent).
- Explain to the patient that mild discomfort will be experienced during the procedure and that spotting for up to a few days after the procedure is expected.
- Educate the patient about the warning signs of complications (e.g., increasing pain, heavy bleeding, and fever).

#### **PROCEDURE**

#### Hysterosalpingography

- 1. Check all equipment to ensure that the setup is complete and in proper working condition.
- 2. Draw up the contrast material and preload the cannula (bubbles may obscure intrauterine disease or be confused with intrauterine polyps).
- Position the patient on a high-resolution image-intensifier fluoroscopy table in the dorsal lithotomy position. An adequate light should be available.
- 4. Perform a bimanual pelvic examination to assess the degree of flexion or retroflexion of the uterus and to exclude pelvic tenderness (the latter is a contraindication to HSG if there is suspected inflammation).
- 5. Insert the vaginal speculum.
- 6. Cleanse the cervix and upper vagina with antiseptic.
- 7. If indicated by the cannula choice, grasp the anterior lip of the cervix with the tenaculum (slowly, to minimize pain).
- 8. Insert the cannula and seat it as indicated by the specific cannula:
  - Inflate the upper balloon, then the lower balloon—Mencini Double Balloon Hysterosalpingography Catheter (Cook-Medical) (see Fig. 144-7).
  - Inflate the upper balloon and set the spring platform—HUI/ Zinnanti (CooperSurgical) (see Figs. 144-5 and 144-11).
  - Inflate the balloon and pull down—pediatric Foley and H/S Elliptosphere (CooperSurgical) (see Fig. 144-6).
  - Insert the cannula and set spring to tenaculum (Jaco).
  - Insert the cannula and seat suction cup onto the cervix, then apply suction to the cup—Thurmond-Rosch movable cup Hysterocath (CookMedical) (see Fig. 144-10).
- 9. Remove the speculum (nonradiopaque plastic speculum may be left in place).
- 10. Place the patient in the recumbent position for fluoroscopy.
- 11. Inject the contrast slowly. Between 1 and 3 mL may be sufficient to show intrauterine detail; greater volumes may obscure small polyps or adhesions. The injection should be viewed concurrently, and a single spot film taken. Upward or downward movement of the tenaculum will often change the degree of flexion to obtain a better view. Warming the dye preprocedurally may decrease associated cramps.
- 12. Continue to inject dye until the tubes start to fill. A spot film at this point may show tubal detail that will be obscured after dye spills.
- Continue to inject dye until intra-abdominal spill of dye is seen bilaterally. A spot film at this point will sometimes show peri-

- tubal detail. A delayed film may be needed to confirm location of dye in peritubal adhesions.
- 14. Rolling the patient from side to side during the procedure sometimes helps the clinician to visualize lesions but increases the radiation exposure.
- 15. If visualization of one tube cannot be accomplished initially, try relaxing tubal spasm by relieving the pressure on the syringe and waiting 1 to 2 minutes.
- 16. Remove the instruments.
- 17. Observe the patient for 30 minutes for allergic reactions and heavy bleeding.
- 18. Selective cannulation of the ostium is briefly done as follows (see Fig. 144-7):
  - Preassemble coaxial catheter portions to be used or add portions as indicated, for the given patient.
  - Place the cervical access catheter (CAC) as previously discussed (catheter type must match the system used).
  - Introduce the uterine ostial access catheter (UOAC) through the CAC under radiologic guidance until the tip reaches the tubal ostium (this may be aided by the injection of a small amount of a contrast agent).
  - Pass the uterine cornual access catheter (UCAC) through the UOAC until the ostium is reached.
  - Advance the guidewire into the tube for a short distance, advance the UCAC over the wire, and then repeat the process until the UCAC is well within the tubal lumen.
  - While holding the UCAC in place, remove the wire.
  - Confirm placement by injecting contrast material into the UCAC.

#### Sonohysterography

- 1. Using the infusion port of the catheter, fill the catheter with sterile normal saline, purging all air. Even a few tiny air bubbles can create difficulties when evaluating the images.
- 2. A brief transvaginal ultrasound should be done prior to the SIS to establish the angle of the uterus and to measure the endometrial stripe. If other than a thin endometrial stripe is noted, a pregnancy test should be ordered prior to insertion of the catheter. Tenderness noted at this point should prompt the question of inflammation and may be a contraindication to continuation with the SIS.
- 3. Position the patient in the lithotomy position and insert a speculum (one-armed Graves speculum is preferred because it will be removed after placement of the catheter and before the reintroduction of the vaginal ultrasound probe).
- 4. Prep the vagina and cervix with antiseptic.
- 5. Insert the SIS catheter of choice and inflate the balloon. If the patient has not had a vaginal delivery, the balloon can frequently be inflated in the endocervix instead of in the endometrial cavity, enhancing the evaluation of the lower uterine segment and decreasing the discomfort.
- 6. Remove the speculum and insert the transvaginal ultrasound transducer into position, taking care not to displace the cannula (see Fig. 144-6).
- While imaging the uterus, slowly inject 5 to 10 mL of contrast agent. In some cases up to 20 mL of normal saline is necessary.
- The uterine distention allows evaluation of the cavity for polyps or other disease.
- Continued injection (especially if Albunex is used) fills the tubes for study; if spillage into the abdomen occurs, patency of at least one fallopian tube is verified.
- 10. If an endometrial biopsy is indicated and a Sonobiopsy Catheter is used, the biopsy is performed without removing the catheter. The saline is removed and suction applied to the catheter while it is moved in and out and rotated at the same time to obtain an endometrial sample (see Fig. 144-9).

#### **COMPLICATIONS**

- Infection rates may be as high as 3% in patients with a prior history of pelvic infection. Antibiotic prophylaxis is indicated in select patients (as mentioned previously) to decrease this risk.
- Tenaculum site bleeding is rare but may require suturing.
- Extravasation of dye into the intravascular space warrants discontinuation of the procedure, especially if an oil-based dye is used (there is a risk of oil pulmonary embolus).
- Granuloma formation after use of an oil-based dye is a rare late complication.
- Perforation of the uterus (or tube with selective cannulization) should prompt discontinuation.
- Rupture of a hydrosalpinx can occur.

#### INTERPRETATION OF RESULTS

Interpretation of results is not reviewed in this chapter, but a few points may be helpful.

- The normal HSG should show (1) a smooth triangular endometrial cavity, (2) a narrow smooth isthmic tube, (3) a progressively enlarging, increasingly convoluted ampullary tube with internal mucosal folds, and (4) spillage into the peritoneal cavity with dispersion between bowel loops.
- The correlation of HSG and laparoscopy may be as poor as 25% false positives and false negatives (the use of selective cannulation may decrease this). Therefore, absolute statements regarding tubal patency and chances for conception should be avoided.
- Uterine anomalies are classified according to Buttram and Gibbons, and may also require SIS or laparoscopy to fully define the abnormality. SIS has the advantage over HSG in classifying uterine anomalies, because it can evaluate the myometrium, as well as the endometrial cavity, without the risk of anesthesia or surgery. Ultrasound of the late menstrual endometrium with three-dimensional (3-D) sonography allows better delineation of these uteri (Fig. 144-12).
- The association of renal with uterine developmental anomalies may be as high as 20%; therefore, renal evaluation may be indicated.

The benefits of HSG over SIS are as follows:

- HSG establishes patency of both fallopian tubes.
- HSG can give the appearance of pelvic adhesions if loculations of dye occur in the adnexa.

 HSG can be "therapeutic" and increase pregnancy rates for unknown reasons if oil-based contrast agent is used (see Table 144-1).

The benefits of SIS over HSG are as follows:

- SIS enables visualization of the entire uterus, including the myometrium as well as the endometrial cavity. It is becoming the gold standard for evaluation of uterine anomalies, and can more accurately differentiate between a bicornuate and a septate uterus, for example (see Fig. 144-12). Adding 3-D ultrasound enables further evaluation, as one can reconstruct and rotate the 3-D uterus for additional views (see Fig. 144-12).
- For patients with abnormal uterine bleeding, SIS will reveal global or focal thickening. If there is focal thickening, from a polyp, for example, it can determine anatomic location and size (Fig. 144-13; and see Fig. 144-2).
- SIS is helpful for evaluating fibroids, particularly if they are submucosal or intracavitary. The degree to which a fibroid extends into the endometrial cavity can be established and help to determine if hysteroscopic removal is feasible.

# Intrauterine Device Insertion

Ashley Christiani

The intrauterine contraceptive device (IUD) has been in use for over five decades and is the most commonly used method of reversible birth control, with current use estimated at over 160 million women worldwide. In the United States, two types of IUDs are available: the *ParaGard T380A*, a copper IUD containing no hormones that may be left in place for 10 years; and the *Mirena Levonorgestrel Intrauterine System (LNG IUS)*, a progesterone-secreting device that is effective for 5 years. The primary mode of action for IUDs is through inhibition of sperm function (thus preventing ova fertilization) through release of endometrial prostaglandins and leukocytes, enzymes, and copper ions. As a secondary effect, the endometrium is typically rendered inhospitable to embryonic implantation. The LNG IUS has additional effects related to hormonal suppression of the endometrium, thickening of cervical mucus, and inhibition of ovulation.

Although IUDs fell out of favor in the United States many years ago after a reported increase in the incidence of pelvic inflammatory disease (PID) and the highly publicized Dalkon Shield lawsuits, contemporary IUDs have reemerged as an excellent option for reversible, long-term birth control owing to their well-demonstrated safety and potential therapeutic effects (Tables 145-1 and 145-2). Numerous studies demonstrate that the risk of PID and upper genital tract infection is low in properly selected patients. Features that make the IUD an attractive form of birth control for many women are an efficacy rate that rivals sterilization, favorable safety profile, ease of use once inserted, and relative lack of systemic effects. Disadvantages include altered bleeding patterns (especially in the first few months after IUD placement), the need for a procedure to place and remove the device, cramping and pain at time of insertion (as well as possibility of increased dysmenorrhea with copper IUDs), risk of expulsion of the device (2% to 10% in first year), and the risk of uterine perforation at the time of the procedure (risk is 1 per 1000 in experienced hands).

#### **INDICATIONS**

- The ideal candidate for an IUD is a parous woman in a stable, mutually monogamous relationship, with no sexually transmitted infection (STI) risk factors who is looking for long-term but reversible birth control. The patient should be willing to check for the presence of IUD threads on a monthly basis.
- The IUD is especially appropriate for women who have difficulty remembering to take oral contraceptives or are intolerant to them, who wish to maintain fertility, and who want to avoid systemic hormones.
- Women older than 35 years of age who are smokers and others with increased risk of thromboembolic events, cardiac disease, hypertension, or other contraindications to hormonal therapy are also good candidates.
- Although not listed as an indication by the company, the LNG IUS may be a preferred contraceptive method in women with endometriosis, dysmenorrhea, hypermenorrhea, or significant

anemia given that menstrual bleeding and cramping generally decrease significantly within 3 to 6 months. Overall blood loss drops approximately 90% and some 20% of women experience absence of bleeding because of the localized progestin effect. Other possible off-label uses of the LNG IUS are to treat endometrial hyperplasia and for postmenopausal women on hormone replacement who are intolerant to oral progestins. The progesterone component provides endometrial lining suppression, decreasing the risk of endometrial hyperplasia and uterine cancer.

- The IUD is also acceptable for women who were once considered poor candidates for the device, including adolescents, nulliparous women, women in nonmonogamous relationships, and those with a history of PID or ectopic pregnancy. Use of the IUD in these populations is reasonable in the context of appropriate screening and counseling regarding side effects and STI prevention (Table 145-3).
- Emergency contraception may be provided with the copper IUD only.

#### **CONTRAINDICATIONS**

The World Health Organization (WHO) Medical Eligibility Criteria provide guidance in risk assessment for the IUD and LNG IUS. The full-eligibility screening tool is available online at www. who.int/reproductive-health/publications/mec/iuds.html. Category 4 indicates unacceptable health risk, Category 3 indicates that the risks generally outweigh the benefits, Category 2 indicates the benefits generally outweigh the risks, and Category 1 indicates no restrictions.

# World Health Organization Category 4 (Unacceptable Health Risk)

#### For All IUDs

- Congenital or acquired uterine cavity malformations that would distort the uterine cavity, making it incompatible with IUD insertion. Includes large fibroids, bicornate uterus, abnormally large or small uterine cavity (axial length <6 cm or >9 cm).
- Pregnancy or suspicion of pregnancy (except in the setting of emergency contraception).
- Immediate postseptic abortion or puerperal sepsis.
- Postpartum endometritis or infected abortion within the past 3 months.
- Current or recent STI (within past 3 months).
- Current or recent PID (within past 3 months).
- Known pelvic tuberculosis (insertion of IUD may substantially worsen the disease).
- Genital bleeding of unknown cause.
- Known or suspected uterine or cervical neoplasia (awaiting treatment).
- Malignant gestational trophoblastic disease.

TABLE 145-1	Rate of Continuation of Contraception	ve
Method at 1	Year	

Method	Continuing Method after I Year
Mirena intrauterine device (IUD)	81%
ParaGard Copper IUD	78%
Oral contraceptive pill	68%
Depo-Provera	56%
Condom	53%
Diaphragm	57%
Spermicide	42%

Data adapted from Trussell J, Kowal D: The essentials of contraception: Efficacy, safety and personal considerations. In Hatcher RA, Trussell J, Stewart F, et al (eds): Contraceptive Technology. New York, Ardent Media, 1998, pp 211–247.

#### For LNG IUS Only

• Breast cancer (Category 1 for copper IUD).

# World Health Organization Category 3 (Risks Generally Outweigh Benefits)

#### For All IUDs

Acquired immunodeficiency syndrome (AIDS) or human immunodeficiency virus (HIV) positive. Some studies suggest it is safe to use IUDs in patients with well-controlled HIV infection, but caution is advised.

<sup>\*</sup>Used without spermicide.

Data adapted from Trussell J, Kowal D: The essentials of contraception: Efficacy, safety and personal considerations. In Hatcher RA, Trussell J, Stewart F, et al (eds): Contraceptive Technology. New York, Ardent Media, 1998, pp 211–247.

- Fewer than 4 weeks postpartum (although <48 hours is Category 2 for copper IUDs).
- Multiple current sexual partners, a partner who is not monogamous or is otherwise at increased risk for STIs, including HIV.
- Benign gestational trophoblastic disease.
- Ovarian cancer (contraindication to IUD insertion, but existing IUD may remain in place until time of treatment if contraception needed).

#### For LNG IUS Only

- Active viral hepatitis (Category 1 for copper IUDs), related to concerns regarding impact of hormonal effect on viral load.
- Active liver disease, including severe decompensated cirrhosis, liver adenoma, or hepatoma (Category 1 for copper IUDs).
- Current deep vein thrombosis (DVT) or pulmonary embolism (Category 1 for copper IUDs).
- History of breast cancer, disease free for 5 years (but Category 1 for copper IUDs).
- Migraines with focal neurologic symptoms for LNG IUS (Category 1 for copper IUDs).

## World Health Organization Category 2 (Benefits Generally Outweigh Risks)

- Nulliparity (or, more specifically, nulligravidity). Although the manufacturers list nulliparity as a contraindication to an IUD, many authorities state that any nulliparous woman who feels confident she can avoid STIs should be considered a possible candidate for an IUD. These women should be warned of the risk of PID and of the slightly elevated risk of IUD expulsion. These women may benefit from cervical priming with misoprostol 400 µg or osmotic laminaria before insertion.
- Recent second-trimester abortion (increased risk of expulsion).
- Heavy or prolonged uterine bleeding (includes regular and irregular patterns).
- Minor anatomic anomalies such as cervical stenosis or laceration or small uterine fibroids that do not distort the uterine cavity or significantly interfere with IUD insertion.
- History of PID without current risk factors for STIs but without subsequent pregnancy (note that if patient has had subsequent pregnancy, risk is reduced to Category 1).
- Vaginitis without cervicitis.
- Complicated valvular heart disease.\*
- Postpartum less than 48 hours for copper IUD (Category 3 for LNG IUS).

#### For Copper IUDs Only

- Endometriosis or severe dysmenorrhea, which may worsen symptoms (Category 1 for LNG IUS).
- Thalassemia (Category 1 for LNG IUS).
- Sickle cell disease (Category 1 for LNG IUS).
- Iron-deficiency anemia (Category 1 for LNG IUS).

#### For LNG IUS Only

- Diabetes (Category 1 for copper IUDs).
- Gallbladder disease (Category 1 for copper IUDs).
- Mild compensated cirrhosis (Category 1 for copper IUDs).
- Obesity (BMI ≥30) (Category 1 for copper IUDs).
- Cardiac risk factors (e.g., smoking, diabetes, advanced age, hypertension, hyperlipidemia, known ischemic heart or vascular disease; Category 1 for copper IUDs).
- History of stroke for LNG IUS (but Category 1 for copper IUDs).
- Recent major surgery with prolonged immobilization (due to DVT risk; Category 1 for copper IUDs).

<sup>&</sup>lt;sup>†</sup>Used with spermicide.

<sup>&</sup>lt;sup>‡</sup>Contains spermicide.

<sup>\*</sup>Prophylactic antibiotics may be advised for insertion (see Chapter 221, Antibiotic Prophylaxis).

Population	Considerations
Adolescents	Despite increased risk of pregnancy, expulsion, and removal for bleeding or pain, the IUD is still more effective than other forms of reversible contraception in this age group, and age should not be the primary determinant of candidate for the device. Rates of infection are similar to those in adults.
Nulliparous women	Nulliparous women have similar rates of infection and efficacy with IUD use compared to multiparous women; however, higher rates of expulsion and discomfort can limit tolerance for the device.
Fertility	Most women, including nulliparous patients, can expect a rapid return to fertility after discontinuing copper or hormone-releasing IUDs. Contrary to common belief, use of a copper IUD does not appear to increase the risk of tubal infertility in nulligravid women in the absence of chlamydial infection.
Prior ectopic pregnancy	The IUD is protective against ectopic pregnancy and is appropriate for women with a history of an ectopic pregnancy
Insertion after abortion	IUD insertion is safe immediately after spontaneous or induced abortion and is not associated with an increased risk operforation or infection. Expulsion rates are higher when inserted immediately after second-trimester abortion.
Insertion postpartum	Postpartum insertion appears to have a higher rate of expulsion, but no increase in perforation or infection. Expulsion is less likely when insertion is performed within 10 minutes of delivery of the placenta compared to 1 to 2 days postpartum. If immediate postpartum insertion is not done, then waiting 4 to 6 weeks is advisable. Only the Paragarc Cu380A has approval for immediate postpartum insertion. The LNG IUS can be inserted at the 6-week postpartum visit. Breast-feeding women can safely use either device.
Use for emergency contraception	The ParaGard IUD can be inserted within 120 hours of unprotected intercourse for emergency contraception with a efficacy of 98.1% in parous women and 92.4% in nulliparous women.
Valvular heart disease	There is no contraindication to use of the IUD in women with uncomplicated valvular heart disease (including mitral valve prolapse and aortic stenosis). Even in women with complicated valvular heart disease, the benefits an IUD generally outweigh risks. Advantages include avoidance of pregnancy risks and those associated with estrogencontaining contraceptives. Prophylactic antibiotics are recommended at the time of insertion to prevent infective endocarditis in those with high-risk valvular heart disease.
Coexistent gynecologic conditions	There is no contraindication to use of the IUD in women with irregular menses, vaginitis, cervical dysplasia or cervical ectropion, a history of benign ovarian cysts, past PID with a subsequent pregnancy, or prior cesarean delivery. In some situations, such as menorrhagia, use of the LNG IUS is therapeutic. The cause of any abnormal bleeding should be defined prior to insertion. It is best to evaluate significant abnormal Pap smears prior to insertion since performing LEEP procedure can be difficult if not impossible to do with the strings in place.
Coexistent chronic medical conditions	There is no contraindication to use of the copper IUD in women with diabetes mellitus, cardiovascular disease, migraine headaches, breast cancer or benign breast disease, smoking, obesity, epilepsy, or liver, gallbladder, or thyroic disease. There is no increased risk of pelvic infection in women with diabetes mellitus. Neither the copper IUD nor LNG IUS adversely affects glycemic control in diabetic patients.
Immunocompromise	IUD use does not enhance the risk of HIV acquisition over that in users of other contraceptives. Limited data suggest no increased risk of PID in HIV-positive IUD users. In conjunction with appropriate condom use, the IUD may be safely used in women with or at risk for HIV infection. However, for women at risk of HIV and other sexually transmitted infections, hormonal contraception may be preferable due to protection against ascending infections.
Cancer	The copper IUD use has been associated with lower risks of endometrial and cervical cancer. The LNG IUS likely reduces the risk of endometrial cancer but may increase risk of breast cancer.
Menopausal women	An IUD inserted for contraception should be removed one year after the last menstrual period in menopausal women.

HIV, human immunodeficiency virus; LEEP, loop electrosurgical excision procedure; PID, pelvic inflammatory disease.

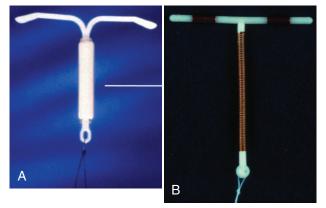

- Migraines (Category 1 for copper IUDs).
- Cervical intraepithelial neoplasia (Category 1 for copper IUDs).

#### **Other Contraindications**

- Allergy to copper (for ParaGard); hypersensitivity to any component of the IUD, including levonorgestrel, silicone, or polyethylene; or any past history of IUD intolerance.
- Wilson's disease (for ParaGard).
- Desire for short-term contraceptive use (may be more cost effective to use any other method).

#### **EQUIPMENT**

- The desired prepackaged IUD (ParaGard, LNG IUS; Fig. 145-1)
- Speculum
- Sterile basin with cotton balls moistened with a water-based antiseptic, such as povidone-iodine (Betadine) or chlorhexidine gluconate
- Ring forceps
- Cervical tenaculum
- Uterine sound

**Figure 145-1** Available intrauterine devices. **A,** Mirena LNG IUS. **B,** ParaGard T380A. (A, Courtesy of Berlex Laboratories, Wayne, NJ. B, Courtesy of Ortho-McNeil Pharmaceutical, Inc., Raritan, NJ.)

- Nonsterile gloves (for bimanual examination before insertion procedure)
- Sterile gloves (for IUD insertion phase)
- Sterile towel to cover tray
- Long suture scissors (to cut IUD threads after insertion)

#### **Optional Equipment**

- Nonsteroidal anti-inflammatory drug (NSAID), to be taken before procedure (e.g., 800 mg ibuprofen).
- Although not generally necessary, local anesthetic may be helpful
  in some patients. Lidocaine 2% without epinephrine may be used
  to perform a paracervical or submucosal block (additional equipment includes 10-mL syringe, needle extender with a 22-gauge
  long needle, Monsel's solution, and cotton-tipped swabs; see
  Chapter 149, Loop Electrosurgical Excision Procedure for Treating Cervical Intraepithelial Neoplasia, and Chapter 173, Paracervical Block, for submucosal injection technique).
- Cervical dilators (see Chapter 136, Cervical Stenosis and Cervical Dilation).

#### PREPROCEDURE PATIENT PREPARATION

A separate office visit for patient counseling, consent, and preparation is advised before the IUD insertion visit. However, current guidelines suggest that the patient may be counseled, evaluated, and have the IUD inserted, if appropriate, on the first visit. A separate visit allows the patient the opportunity to review the material, consider her contraceptive options, ask questions, examine sample IUDs, and plan for the procedure. This visit also provides the clinician with the opportunity to assess potential risks and benefits of IUD insertion, provide counseling, address common myths and misconceptions regarding the device (Table 145-4), and perform the screening evaluation. An insertion date is more easily planned and scheduled at another time.

#### **Patient Counseling and Consent**

Federal guidelines require that patients be given an IUD patient information brochure as part of the consent process before IUD insertion. Brochures are provided through the manufacturers of ParaGard and the Mirena LNG IUS (see the "Suppliers" section). These brochures are excellent resources and can serve as consent documents when the patient reviews the checklists and signs the forms. The clinician should confirm that the patient understands her risks, benefits, and alternatives to IUD placement and the common side effects experienced with this form of contraception. The clinician should advise of the cramping and discomfort associated with IUD insertion as well as removal and the potential for transient nausea, dizziness, or faintness during and immediately after the procedure.

It is common to have *mild spotting and cramping* for a few days after the procedure and up to 8 weeks after insertion of IUDs, but if these symptoms are severe or the discomfort is not alleviated with over-the-counter analysics, the patient will need medical evaluation.

Patients must be willing to check for the presence of IUD threads after the first menstrual period and each month thereafter. If the threads cannot be found or seem to be migrating upward, the patient must notify her physician. Although patients may expect reliable birth control immediately after IUD insertion, some authorities recommend 1 to 2 weeks of pelvic rest after the procedure to minimize risk of infection and other complications. The importance of a mutually monogamous relationship should be emphasized with the explanation that any new partners will increase the risk of PID while the IUD is in place. Although the IUD has not been shown to increase risk of cervical dysplasia, women using this form of contraception may be less likely to present for routine gynecologic examinations and should be specifically instructed to continue regularly scheduled pelvic examinations and Pap smears. After insertion, the patient should be given an identification card or form with the name and design of her IUD, the date of insertion and recommended date for removal, and the date of her follow-up appointment.

#### **Screening Evaluation**

Before IUD insertion, a Pap smear (within 6 months) and pelvic examination along with any appropriate STI screening should be performed and the results documented as negative. The pelvic examination should include assessment of uterine size and position, examination for signs of cervicitis or vaginitis, and evaluation of the general morphology of the cervix and os, including signs of cervical stenosis.

#### **Timing of Procedure**

Because of higher risk of expulsion during menses (5% risk of expulsion with insertion during the first 5 days of the menstrual cycle, compared with 2% risk with luteal-phase insertions), and slightly higher risk of postinsertion pain or bleeding with luteal-phase insertions, the optimal timing is the late follicular phase (day 5 to 10 of cycle). However, the IUD may be inserted at any time provided the patient is consistently using a reliable method of contraception, has been abstinent since the last menses, or is within 5 days of a single act of unprotected intercourse and desires emergency contraception with a copper IUD.

#### **Pretreatment**

Patients should consider taking ibuprofen (600 to 800 mg) or other NSAID 45 to 60 minutes before IUD insertion to minimize cramping and discomfort during the procedure. Local anesthetic is usually

TABLE 145-4 Myths and Misconceptions about IUDs					
Myth	Fact				
IUDs are abortifacients.	IUDs prevent fertilization and thus are true contraceptives.				
IUDs increase the risk of ectopic pregnancy.	IUDs significantly reduce a woman's risk of an ectopic pregnancy because the IUD prevents all types of pregnancies. Should a pregnancy occur with an IUD in place, the ratio of ectopic to intrauterine pregnancies may be increased.				
IUDs expose the provider to medoicolegal risk.	In past decades, product liability suits against manufacturers alleged inherently unsafe products or failure to warn of risks.  Today, IUDs have been judged safe by the U.S. Food and Drug Administration. Package inserts and patient brochures provide extensive information about risks and benefits. Hence, litigation related to IUDs has virtually disappeared.				
IUDs increase the risk of PID.	The IUD itself appears to have no effect on the risk of upper genital tract infection. Rather, the insertion process carries a small, transient risk in some women. The risk of PID in appropriately selected IUD candidates is so small that prophylactic antibiotics are not warranted.				

PID, pelvic inflammatory disease.

From Stewart F, Gary K: Intrauterine devices (IUDs). Hatcher RA, Trussell J, Stewart F, et al (eds): Contraceptive Technology. New York, Ardent Media, 1998, pp 511–543.

not necessary but may be helpful in the apprehensive patient, particularly those at risk for significant discomfort (nulliparas, those requiring cervical dilation, those with history of pain with prior cervical procedures) or vasovagal reaction. If desired, use lidocaine 1% to 2% without epinephrine to perform a paracervical or submucosal block (see Chapter 149, Loop Electrosurgical Excision Procedure for Treating Cervical Intraepithelial Neoplasia, and Chapter 173. Paracervical Block, for the submucosal injection technique). Some clinicians advocate the use of topical benzocaine spray (e.g., Hurricaine); however, studies with patients undergoing endometrial biopsy failed to demonstrate a pain control benefit compared with placebo. Per current American College of Obstetricians and Gynecologists (ACOG) and American Heart Association (AHA) guidelines, routine antibiotic prophylaxis for PID prevention and for bacterial endocarditis is not recommended (see Chapter 221, Antibiotic Prophylaxis).

#### **TECHNIQUE**

The IUD insertion technique described here provides general guidelines for the procedure. For further details, the clinician should refer to the physician insert provided by each manufacturer in the respective packaging.

#### Initial Steps (Both IUDs)

Ensure that the patient understands the method of and alternatives to IUD placement and that the consent form has been signed. Confirm that the patient is still a candidate for the IUD (i.e., is in a stable, monogamous relationship and has not developed any contraindications as listed previously). Confirm a negative Pap smear result.

- Confirm a negative pregnancy test if there is any question of pregnancy.
- 3. Reassess the need for an NSAID, antibiotic prophylaxis (not routinely recommended), heating pad (low to medium heat) for the patient's abdomen, or other special accommodations.
- 4. Perform a bimanual pelvic examination to reconfirm the size, position, consistency, and mobility of the uterus and to screen for the presence of any signs or symptoms of acute pelvic infection. A speculum examination may be repeated at this time if desired.
- 5. Change to sterile gloves and observe sterile technique from this point on in the procedure.
- Prepare a sterile field containing the supplies discussed previously. Request an assistant, if desired.
- With the patient in the lithotomy position, insert a warm, sterile speculum into the vagina. The cervix should be well visualized and the os centered in the midline.
- 8. Using the ring forceps, cleanse the cervix with the antiseptic-soaked cotton balls.
- Perform a paracervical (see Chapter 173, Paracervical Block) or submucosal block if desired.
- 10. Clamp a single-tooth tenaculum to the anterior lip of the cervix. It may be helpful to ask the patient to cough as you apply the device or to inject 1 to 2 mL of lidocaine into the tenaculum site before placement. Apply gentle downward traction on the tenaculum to correct for any angulation and to stabilize the cervix.
- 11. Gently and slowly sound the uterus. Careful technique will decrease the patient's discomfort and the risk of perforation, laceration, and other complications. The uterine depth should be between 6.5 and 8.5 cm. Do not place an IUD if the depth is outside the normal range (there is an increased risk of

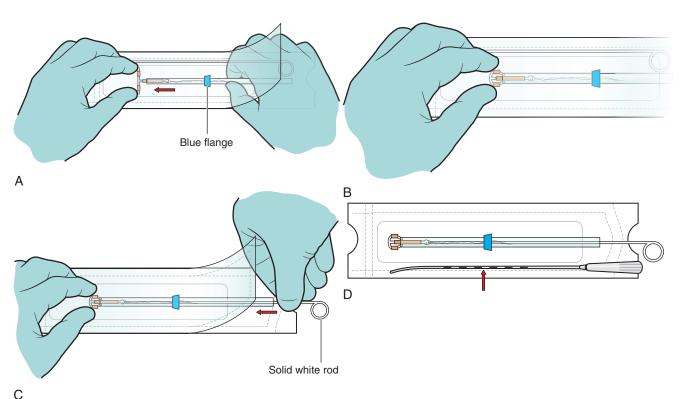

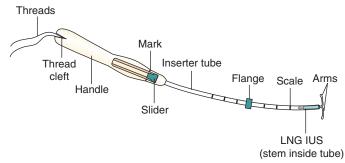

Figure 145-2 Loading the ParaGard intrauterine device (IUD) using the "no-touch" technique just before insertion. **A,** After the bimanual examination and antiseptic solution preparation and after the uterus has been sounded, the IUD is inserted into the hollow inserter tube. **B,** The arms are bent down and inserted just far enough to retain them in the tube. **C,** The solid white inserter rod is placed into the hollow insertion tube from the other end so that it just touches the bottom of the vertical arm of the IUD. **D,** The blue flange is set so that the distance from the tip of the IUD to the flange is the same distance as the depth of the uterus (as determined by the uterine sound; *red arrow*). (Redrawn from Pfenninger JL: Techniques for inserting an IUD. Fam Pract Recertification 14:131–138, 1992.)

**Figure 145-3** Mirena Levonorgestrel Intrauterine System (LNG IUS) and inserter. (Redrawn from Berlex Laboratories, Wayne, NJ.)

- complications in this setting). If the sound cannot be inserted because of stenosis, dilate the cervix (see Chapter 136, Cervical Stenosis and Cervical Dilation).
- 12. Prepare the IUD/IUS for insertion. The two units are totally different. The *inserter tube* refers to the hollow cylinder in which the IUD fits. It may be possible to load the ParaGard IUD into the inserter while it is still in the original packaging. This is referred to as the "no-touch technique" and is described in the packaging information of IUDs that provide this loading option (Fig. 145-2). Alternatively, sterile gloves are used to "load" the unit by folding the arms down and inserting them in the inserter tube. The inserter "rod" for the ParaGard refers to the solid trocar that fits inside the inserter tube. Figure 145-3 is a graphic depiction of the Mirena IUS. Loading this system is quite different and will be shown as part of the procedure in Figure 145-5.
- 13. Insert the chosen IUD, using the appropriate technique for the ParaGard or LNG IUS.

#### **ParaGard Insertion**

After following the previous initial steps, insert the ParaGard IUD as follows (Fig. 145-4):

- Make certain that the horizontal arms of the IUD are parallel to the horizontal orientation of the blue flange to ensure proper placement in the uterus. Slide the blue flange so it is the same distance from the tip of the inserter tube as the depth the uterus sounded, maintaining the horizontal orientation.
- 2. Grasping with the single-tooth tenaculum, insert the IUD inserter unit into the cervical canal up to the flange (see Fig. 145-4A). You may wish to have an assistant hold the tenaculum. With the solid white rod in your dominant hand, use the other hand to withdraw the clear plastic inserter tube toward you approximately 2 cm as the white rod is held in place (see Fig. 145-4B). This maneuver will allow the IUD to "fall" into place. Pushing in on the solid rod could cause a perforation. A small "pop" can often be felt as the IUD unfolds.
- 3. Now, while holding the white rod stable, gently and slowly push the hollow tube inserter toward the fundus until resistance is felt to allow "high placement" of the IUD (see Fig. 145-4C[1]). Fundal placement of the IUD decreases the risk of expulsion, accidental pregnancy, and other complications. Withdraw the solid rod only (see Fig. 145-4C[2]). Do not withdraw the tube before removing the rod first. The strings are inside the tube and compressed against the tube by the rod. Pulling both out at the same time could immediately pull out the IUD.
- 4. Withdraw the insertion tube (see Fig. 145-4D).
- Complete the procedure as noted in the "Completion of Procedure" section.

#### **LNG IUS Insertion**

After following the initial steps provided previously, insert the LNG IUS (Mirena) as follows (Fig. 145-5):

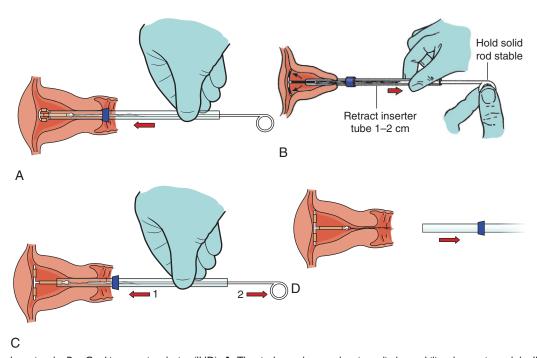

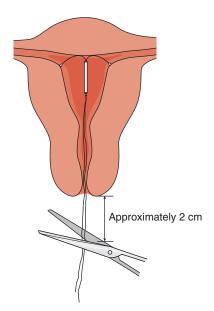

Figure 145-4 Inserting the ParaGard intrauterine device (IUD). **A,** The single-tooth tenaculum is applied to stabilize the cervix, and the IUD–inserter unit is placed into the cervical canal up to the flange. **B,** While an assistant holds the tenaculum, the clinician holds the solid white rod stable in the dominant hand and withdraws the insertion tube approximately 2 cm. **C,** 1, The inserting tube (with the rod held stable and still in place) is gently advanced to ensure high placement of IUD; 2, the solid inserting rod is withdrawn while holding the *tube* steady. **D,** The insertion tube is withdrawn and the threads are cut, ensuring adequate length. (Redrawn from Pfenninger JL: Techniques for inserting an IUD. Fam Pract Recertification 14:131–138, 1992.)

Figure 145-5 Loading and inserting the Mirena Levonorgestrel Intrauterine System (LNG IUS) using sterile glove technique. A and B, The package is opened. The LNG IUS is prepared for insertion. C, The upper end of the flange Slider is set at the uterine depth found with sounding.  ${\bf D}$ , The LNG IUS is inserted with the flange 1.5 to 2 cm from the ectocervix. E, The arms are released by pulling the slider back to the mark. F, For fundal positioning, the clinician holds the slider in position at the mark and pushes the inserter gently inward until the flange touches the cervix. The LNG IUS should now be in the fundal position. G, Finally, the LNG IUS is released by pulling the slider all the way back, which releases the strings. The insertion tube is then removed. Cut the strings to leave 2 to 3 cm visible outside the cervix. (Courtesy of the Association of Reproductive Health Professionals, Ithaca, NY, copyright 2000, used by permission. B (center), Redrawn from Association of Reproductive Health Professionals, Ithaca, NY.) Arms folded up Pull both threads Insertion tube all the way back Fix threads in until small knobs cleft in handle on IUS occlude the tubal opening Mirena IUS is withdrawn into insertion tube; be sure arms are horizontal; do this В just before insertion Uterine depth by sounding Sound measure Flange 1.5-2 cm Release arms by pulling slider back to mark Ε Set the flange depth D Partially insert the IUS Pull slider all the way back Release strings Push inserter until flange touches cervix G

- 1. After opening the sterile package, release the threads, making sure the slider is in furthest position from you. Use the sterile packaging to rotate the arms of the system to be horizontal when the lettering on the handle is facing upward (see Fig. 145-5A).
- 2. Load the LNG IUS for insertion. Pull on both threads to draw the LNG IUS into the insertion tube. The arms will fold upward (the ParaGard arms fold down). The knobs at the ends of the arms should occlude the open end of the inserter. Fix the threads tightly in the cleft at the near end of the inserter shaft (see Fig. 145-5B).
- 3. Set the upper end of the flange at the uterine depth measured previously (see Fig. 145-5C).
- 4. Hold the slider firmly with the forefinger or thumb in the furthermost position, and advance the inserter into the cervical canal until the flange is about 1.5 to 2 cm from the cervix. This is a significant difference from the method of inserting the ParaGard. Keeping the flange 1.5 to 2 cm away from the cervical os allows sufficient space for the arms to open within the uterus (see Fig. 145-5D).
- 5. While holding the inserter steady, release the arms of the LNG IUS by pulling the slider back until it reaches the mark (i.e., raised horizontal line; see Fig. 145-5E).
- 6. Stabilize the slider in the current position and push the inserter gently inward until the flange now touches the cervix. The LNG IUS should now be in the fundal position (see Fig. 145-5F).
- 7. Holding the inserter rod steady, release the LNG IUS by pulling the slider all the way back. The threads will be released automatically (see Fig. 145-5G). Remove the inserter carefully from the uterus.
- 8. Complete the procedure as noted in the next section.

#### **Completion of Procedure**

- After insertion, the IUD should remain within the uterine cavity. If any portion of the device is visible or protruding from the endocervical canal, the device should be removed by pulling the string, and then a sterile device from a new package should be used.
- 2. After the inserter is removed from the uterus, cut the IUD threads to a length of 2 to 3 cm beyond the os (Fig. 145-6). It is

**Figure 145-6** Threads are cut (leaving about 2 to 3 cm visible outside the cervix). (Redrawn from Berlex Laboratories, Wayne, NJ.)

- better to leave the threads too long than too short because they can be shortened on subsequent visits if necessary and short threads may be irritating or painful for a male partner.
- Remove the tenaculum and observe the site for bleeding. If bleeding is seen, apply pressure or Monsel's solution to achieve hemostasis.
- 4. Remove the speculum.
- Provide postprocedure counseling to the patient and arrange a follow-up appointment for an IUD and symptom check after the first postinsertion menses.
- 6. Complete the encounter form (Fig. 145-7) or dictate a complete note.

#### **COMMON ERRORS**

- Cutting the strings too short
- Device slips back out during the insertion process
- Contaminating the IUD
- Not doing a pelvic examination and determining the uterine position
- Not using a tenaculum to straighten the cervical angle
- The last common error that can cause a significant problem is pushing in on the inserter rod (for the ParaGard) instead of pulling back on the inserter tube (see Fig. 145-4B) to "release" the IUD. Pushing in on the rod could cause a perforation.

#### **Short Strings**

It is better to cut the strings too long than to risk cutting them too short. Short strings may make it difficult for the patient to check her strings and can cause discomfort to her partner (see later). If the strings are accidentally cut too short (<2 cm), the clinician should consider inserting a new device. If the patient is able to reach the strings and prefers to keep the IUD in place, she can be monitored with instructions to return for any difficulty or complications.

#### Contamination of the IUD

Contamination of the device most commonly occurs when the IUD or the distal tip of the insertion tube is touched with a nonsterile hand during the preparation or insertion process. If this occurs, a new package must be opened and the procedure repeated with a sterile device. The contaminated IUDs may be returned to the manufacturer for refund.

#### **COMPLICATIONS**

Placement of an IUD is a relatively safe procedure with significantly less morbidity and mortality than pregnancy and delivery. The IUD itself is generally well tolerated, as demonstrated by the 1-year continuation rate for this birth control method compared with other methods. Nonetheless, it is important to counsel patients on the risk of complications and common side effects of the IUD, which are discussed in the following sections.

#### Vasovagal Reaction

Some women experience vasovagal reactions with instrumentation of the cervix or immediately after insertion. Such reactions may include lightheadedness, hypotension, bradycardia, nausea, or even syncope. If such symptoms occur, the patient should be kept in the supine position and given supportive care until the reaction resolves. Rarely do such symptoms persist. In severe cases a paracervical block may be done (or repeated) or atropine (0.4 to 0.6) can be given intramuscularly or intravenously. Occasionally the IUD may need to be removed.

#### **Perforation**

Perforation of the uterus or cervix is extremely rare (<0.1%). It generally occurs at the time of uterine sounding or occasionally with insertion. Perforation should be suspected if the sound enters the uterine cavity more than 12 cm and uterine palpation has indicated a normal size. The perforation itself is usually painless and often occurs in the setting of forceful pressure through a tight cervical

os. Should perforation be suspected, the clinician should pull out the IUD (if already inserted) and observe the patient for 30 minutes. If stable, the patient can be discharged and told to report any signs of infection, abdominal pain, rapid pulse, or shortness of breath. Usually there is an uncomplicated resolution, and insertion can be attempted again in 6 to 8 weeks (no prophylactic antibiotics are indicated). Unstable patients may require immediate surgical consultation.

#### **Uterine Bleeding and Cramping**

Intrauterine devices may cause abdominal or low back pain and cramping, as well as irregular uterine bleeding, particularly in the first 3 months of use. Some women will have heavier bleeding and increased dysmenorrhea with the IUD, particularly when using the ParaGard. Conversely, approximately 20% of women using the Mirena LNG IUS will cease having periods after 3 to 6 months. Menstruation returns rapidly once the device is removed.

#### **Spontaneous Expulsion**

Although uncommon, most IUD expulsions occur within the first 6 months after insertion. The patient may experience cramping, pain, vaginal discharge, abnormal vaginal spotting, dyspareunia, or lengthening of the IUD strings. However, expulsion may be asymptomatic. For this reason the patient should be instructed to check for IUD strings each month after menstruation. Occasionally the IUD will become lodged in the cervical os, which may cause cramping and discomfort. In this case, the IUD should be removed and a new one may be placed if desired. If an IUD is spontaneously passed, is removed because of a complication, or becomes contaminated during the insertion process, it may be returned to the company for a free replacement.

#### **Embedded or Lost Intrauterine Device String**

Missing strings may indicate unsuspected perforation or spontaneous expulsion (see previous section), or migration of the IUD into the endometrial cavity. If the strings are not visible in the os, the clinician should first rule out pregnancy. Ultrasonography may quickly confirm intrauterine location. If the IUD is in place, nothing needs to be done. If the patient desires removal of an IUD whose strings are not visible in the os, special procedures may assist in recovering the IUD (see Chapter 146, Intrauterine Device Removal). Occasionally the IUD may become embedded in the uterine lining, which complicates removal and may necessitate cervical dilation and instrumentation to remove the device.

#### Partner Discomfort (due to IUD Strings)

The IUD strings should be cut to a length of 2 to 3 cm from the external os. It is preferable to leave the strings slightly too long than to risk trimming them too short, which may cause irritation to the partner during intercourse. If the partner complains of penile discomfort (a barblike sensation), the strings can be trimmed further, or the device may need to be replaced. Strings that are too long may be trimmed. Strings that lengthen over time may be a sign of impending expulsion.

#### **Contraception Failure**

Although rare (<1%), pregnancy is possible, even with the IUD in place. In this event, the patient must immediately be assessed for ectopic pregnancy. Although patients with IUDs do not have a higher ectopic pregnancy rate (the risk is actually lower), if pregnancy does occur, nearly 50% will be extrauterine. The IUD should be promptly removed if the woman is in the early stages of pregnancy regardless of whether she desires to continue the pregnancy. Although there is a risk of inducing abortion with removal of an IUD, if it is left in place there is a significant risk of premature labor, sepsis, and spontaneous abortion. Whether the IUD is removed or left in place, there is no increased risk of fetal anomalies.

#### **Pelvic Inflammatory Disease**

The risk of PID is elevated only the first 20 days after IUD insertion or in the setting of exposure to a new sexual partner. If the clinician

suspects PID, it should be promptly treated according to Centers for Disease Control and Prevention (CDC) guidelines, with initiation of antibiotics before IUD removal.\* A new IUD may be placed 3 months after resolution of the infection. However, because of the risk of recurrent STIs and PID, other contraceptive options should be strongly considered.

#### **Actinomyces**

Actinomyces is an anaerobic, gram-positive bacterium. It is more frequently found in IUD users (on routine Pap smear) and is generally asymptomatic. Most authorities recommend removal of the device and antibiotic treatment only in the presence of clinical symptoms. Rarely do the bacteria cause a systemic problem in healthy individuals, but if present or past infection is known, it is best not to insert the IUD because Actinomyces preferentially grows on foreign bodies.

#### **Ovarian Cysts**

Ovarian cysts may develop in patients using the Mirena LNG IUS because of hormonal stimulation. Enlarged follicles are seen in about 12% of LNG IUS users. Most of the cysts are asymptomatic and self-limiting, but on occasion they may cause pelvic pain or dyspareunia.

#### Hormonal Side Effects and Use during Lactation

Hormone-containing IUDs, such as the LNG IUS, may have side effects such as mood changes, acne, headache, breast tenderness, dysmenorrhea, nervousness, vaginitis, hypertension, and nausea. Weight gain is usually not a problem. Other forms of contraception may be preferable for lactating women.

#### Pap Smears and Cervical Dysplasia

Although no known association has been shown between cervical dysplasia and use of the IUD, it is essential that the Pap smear be normal before insertion. Should the patient present with abnormality on her Pap smear, the IUD may complicate the process of cervical and endocervical sampling and procedures such as the loop electrosurgical excision procedure or conization. Because patients using IUDs do not require annual renewal of their contraception, they are at greater risk of neglecting their regular Pap smears. When treating these patients, the clinician should emphasize that they must return for their routine Pap smear and pelvic examinations.

#### POSTPROCEDURE PATIENT EDUCATION

- Give the patient a copy of the IUD handout provided by the manufacturer, including the name and design, the date of insertion, and recommended date for removal. Discuss the following:
  - The patient should check for the presence of IUD strings after each menstruation.
  - The patient should be clear on the signs and symptoms of IUD expulsion, infection, and other possible complications. Instruct her to return for fever, worsening pelvic or abdominal pain, foul-smelling or abnormal vaginal discharge, excessive bleeding (other than spotting for a few months), pain with intercourse, prolonged amenorrhea, any type of genital lesions, or signs of STI or pregnancy.

<sup>\*</sup>WHO guidelines state that in resource-poor settings, it is an option to treat mild to moderate PID without removal of the device.

- Reiterate that the IUD will not protect her from infection from HIV, herpes simplex virus, human papillomavirus, *Chlamydia*, gonorrhea, or any other STI and she must take precautions to avoid these infections.
- A routine follow-up examination to check for strings and review symptoms is scheduled for 1 to 3 months. The IUD is removed when the patient desires pregnancy or as indicated by the manufacturer. The ParaGard IUD should be replaced after 10 years and the Mirena LNG IUS should be replaced after 5 years.

#### **CONCLUSION**

The safety issues and misconceptions that plagued IUDs in the past have largely been resolved, offering patients an excellent option for long-term, reversible contraception. IUDs have high efficacy; require little maintenance; provide long-term, yet reversible, contraception; and are cheaper than birth control pills over a 5-year period. The LNG IUS offers the benefit of decreased vaginal bleeding and may be used in hormone replacement to protect against uterine malignancy and hyperplasia. Conversely, the copper IUD offers the potential advantage of being hormone free.

### INTRAUTERINE DEVICE REMOVAL

Ashley Christiani

Generally, intrauterine contraceptive device (IUD) removal is a simple and uncomplicated procedure that takes only a few minutes. The rare case in which the IUD string is not visible ("lost" IUD) presents a more challenging situation.

#### **INDICATIONS**

- Desire for pregnancy
- Postmenopause (no need for contraception)
- Pregnancy confirmed (early)
- Pelvic infection
- Before loop electrosurgical excision procedure (LEEP)/conization (but with careful precautions, a LEEP can be performed without cutting the string)
- Patient intolerance: pain, bleeding, other
- Manufacturer recommendations
  - ParaGard T380: 10 years
  - Mirena: 5 years
- Inability to identify the strings

#### **CONTRAINDICATIONS**

- Advanced pregnancy (second or third trimester; generally contraindicated because of risk of spontaneous abortion)
- Suspected extrauterine location

#### PREPROCEDURE PATIENT PREPARATION

#### **Patient Counseling and Consent**

Although typically a straightforward and simple procedure, as with any other procedure, patients should receive counseling on the risks, benefits, and alternatives to IUD removal and provided a general overview of what to expect during the process. Depending on the reason for IUD removal, appropriate discussion of contraceptive options, preconception counseling, or management of menopause should be discussed. The clinician should advise of possible cramping and discomfort associated with IUD removal as well as the potential for transient nausea, dizziness, or faintness during and immediately after the procedure. Mild spotting and cramping may occur.

#### **Pretreatment**

Patients may consider taking ibuprofen (600 to 800 mg) or other nonsteroidal anti-inflammatory drug 45 to 60 minutes before IUD removal to minimize cramping and discomfort during the procedure. Local anesthetic is usually not necessary, but may be helpful in the case of a complicated removal, particularly in those at risk for significant discomfort (nulliparas, those requiring cervical dilation, those with history of pain with prior cervical procedures) or vasovagal reaction. In this case, lidocaine 1% to 2% without epinephrine may be used to perform a paracervical or submucosal block (see

Chapter 149, Loop Electrosurgical Excision Procedure for Treating Cervical Intraepithelial Neoplasia, and Chapter 173, Paracervical Block, for the submucosal injection technique).

#### **TECHNIQUE**

#### Removal with Visible IUD Strings

The usual IUD removal is straightforward, and there is no need for sterile technique. Insert the speculum and visualize the IUD strings. Using ring forceps, grasp the strings and pull toward the introitus in a firm and deliberate motion until the IUD is delivered. The patient will likely experience momentary discomfort, which may be prevented somewhat by premedicating with 800 mg of ibuprofen. Remove the speculum and send the patient home. Some minor spotting may be expected for a few days. There is no need to culture the IUD unless infection is suspected.

#### Removal when IUD Strings Are Not Visible

If the speculum is inserted and IUD strings cannot be visualized after a diligent search, one of several approaches may be used. *First*, try using a Cytobrush or similar instrument and insert the brush portion the full depth into the cervical canal (approximately 2 cm). After insertion, rotate and extract the brush in a continuous motion. Repeat several times if needed. In one study, 24 of 27 lost strings were retrieved in this maneuver when other methods had failed.

If this fails, try a *second* method. Insert a long-handled alligator forceps or other hemostat-like instrument such as a uterine packing forceps into the os, with the instrument opened as much as the os will allow. Close the jaws in a blind attempt to catch any strings that may be present. If the strings are indeed grasped, resistance will be felt when the instrument is removed. Carry out this maneuver four or five times in an attempt to grasp the strings. If unsuccessful, or if the os is too small, other methods will be needed to find the strings.

A *third* approach uses an endocervical speculum along with a colposcope to identify the strings. Frequently, the end of the string is just within the os. Once visualized, it is much more easily grasped with forceps and removed.

Should these techniques fail, proceed with a more invasive *fourth option* (see Chapter 136, Cervical Stenosis and Cervical Dilation, for the instrumentation to be used). Perform a bimanual examination to identify the position of the uterus. Prepare the area with an antiseptic solution. Grasp the anterior lip with a single-toothed cervical tenaculum and apply slight traction to straighten the uterus. A uterine sound may be used to dilate the internal os if needed. An IUD remover is then used to enter the intrauterine cavity (Fig. 146-1). Using the larger-sized instruments will prevent or minimize the potential for perforation of the uterus. The double IUD extractor and flexible IUD hook are commonly used. The double IUD extractor resembles a crochet hook that "hooks" the IUC (Fig. 146-2). Use a twist-and-pull motion to "catch" the IUD.

Figure 146-1 Intrauterine device (IUD) removal instruments. From top to bottom: simple IUD hook, universal IUD hook, double IUD extractor, and flexible IUD hook.

Frequent, repeated passes are often needed. The flexible IUD hook is actually a forceps. Insert the stem into the uterus and compress the handle to open the jaws. When the handle is released, the jaws grasp the IUD as they close. Then withdraw the unit. With either instrument, if the string or the IUD is grasped, resistance will be felt.

#### **Embedded IUDs**

If the IUD has been in place for a significant length of time, it may have become embedded in the endometrium and significant force will be required to remove it. Firm pressure rarely if ever breaks the strings. If the force seems to be extreme, there is excessive pain, or there is any question whether the IUD is still in place, it may be best to defer removal. Although a flat-plate radiograph of the abdomen will identify whether the IUD is present (IUDs are radiopaque), the x-ray film will not indicate whether the IUD is intrauterine. A pelvic ultrasonographic examination, on the other hand,

Figure 146-2 Double intrauterine device (IUD) extractor after retrieving a "lost" IUD (ParaGard T380).

will confirm whether it is present and whether it is intrauterine. If the IUD has moved to an extrauterine position, surgery will be

If an intrauterine IUD is confirmed by ultrasonography, the patient must return for a visit when further, more aggressive attempts can be made to remove it. If all else fails, the patient may require a dilation and curettage procedure, with the IUD removed under anesthesia or with the aid of a hysteroscope.

No prophylactic antibiotics are needed.

#### **COMPLICATIONS**

Other than slight discomfort and the possibility of vasovagal reactions, there are no significant complications from routine IUD removal. If other instrumentation is required because of lost strings, rare complications include perforation, infection, and bleeding. If the IUD is being removed in the context of pregnancy, there is significant risk of miscarriage, with rates as high as 50% to 60% in some studies.

#### POSTPROCEDURE PATIENT EDUCATION

Provide contraception, preconception counseling, or hormone replacement and menopause counseling as appropriate. If the patient desires to continue IUD use, there is no need to delay insertion. An IUD may be removed and a new IUD (same or different type) can be inserted at the same visit (see Chapter 145, Intrauterine Device Insertion).

# Insertion and Removal of Implanon

Stephen A. Grochmal • Dale A. Patterson

Implanon is an implantable contraceptive device that functions like other progestin-based contraceptives by developing a thick, hostile cervical mucus and eventual atrophy of the uterine endometrium. Compared to the original Norplant System, Implanon appears to cause a greater inhibition of ovulation in patients. Implanon is designed as a single implant measuring 4 cm long with a diameter of 2 mm and an outer structural membrane composed of ethylene vinyl acetate (EVA) copolymer (Fig. 147-1). This copolymer outer membrane may not react with the surrounding tissue as much as Norplant did, leading to less tissue fibrosis; thus permitting easier extraction when its content is exhausted. The implant core contains 68 mg of etonogestrel in EVA. The progestin is released initially at the rate of 60 ug/day in weeks 5 to 6 of use and then decreases to 35 to 45 µg/day at the end of the first year. The released amount of etonogestrel continues to decrease to 30 to 40 µg/day and 25 to 30 µg/day at 2 and 3 years of use, respectively. Implanon is effective for 3 years and has a shelf life of 5 years. The implant is placed in the subcutaneous tissue of the upper arm with a 19-gauge disposable, preloaded inserter. The insertion is a minor surgical procedure performed in the office. Implanon was approved in July 2006 by the U.S. Food and Drug Administration (FDA).

#### **INDICATIONS**

Implanon is used for contraception.

#### **CONTRAINDICATIONS**

#### **Absolute**

Pregnancy is an absolute contraindication.

#### **Relative**

- Thromboembolism
- Breast cancer
- Hepatic disorders
- Unexplained abnormal vaginal bleeding
- Hypersensitivity to the components of the product

A detailed discussion of relative risks is available in the complete prescribing information at: www.implanon-usa.com/hcp.

#### **EQUIPMENT**

- Examination table
- Sterile surgical drapes and gloves, antiseptic solution, sterile skin marker
- Local anesthetic (1% lidocaine without epinephrine), syringes (3 mL), and needles (25 to 27½ g)

- Sterile gauze, adhesive bandage (self-adhesive wrap like Coban), pressure bandage
- Implanon product kit (Fig. 147-2) (no. 11 blade, straight and curved mosquito clamps, and forceps are needed for removal)

#### **PRECAUTIONS**

Although progestin-containing contraceptives have not been shown to cause birth defects, it is imperative to ensure that a patient is not pregnant prior to inserting Implanon. If a patient is found to be pregnant or becomes pregnant after insertion, the device should be removed.

Caution is also advised in patients with bleeding disorders and patients taking anticoagulants. Implanon may be an appropriate contraceptive for these patients, but precautions should be taken to minimize bleeding.

#### PREPROCEDURE PATIENT EDUCATION

Implanon is more than 99% effective, and when the device is inserted correctly risk of pregnancy is less than 1 per 100 women who use it. Approximately 82% of women continue to use Implanon for 2 or more years. Implanon may be less effective in women who are overweight or are taking certain types of medications. Contraception with progestins is very useful in patients with known hepatic disease, hypertension, psychosis, mental retardation, or a history of thromboembolism. It should be noted that the manufacturer lists thromboembolism, hepatic disorders, and breast cancer as contraindications to the use of Implanon but that clinical practice has shown that progestin-based contraceptives are safe in these patients and preferred over estrogen-containing products.

The implant must be removed after all the progestin is released, generally by the end of the third year. Women should be informed that Implanon does not protect against human immunodeficiency virus (HIV) or other sexually transmitted diseases. A detailed patient consent form is available from the manufacturer's website and online at www.expertconsult.com.

#### **ADVANTAGES**

- Menstrual: Menstrual and ovulatory discomfort and cramping are decreased. There is less bleeding as compared to other implant devices, with more consistent amenorrhea reported (20% at 1 year). In Implanon users, uterine pain was reduced or eliminated in 88% of women previously experiencing dysmenorrhea.
- Sexual and psychological: Sexual intercourse may be more pleasurable because fear of pregnancy is reduced, allowing for more spontaneity.
- Risk of cancer: None known.

**Figure 147-1** Implanon device. (Courtesy of Schering-Plough Corp., Kenilworth, NJ.)

 Additional factors: There was a high continuation rate reported in the clinical trials, and asymptomatic follicular cysts were less common than with users of Mirena or Norplant. The single implant permits quick removal.

#### **DISADVANTAGES**

- Menstrual: Amenorrhea and oligomenorrhea are commonly reported. A more common patient complaint is persistent irregular and less predictable menstrual bleeding.
- Sexual and psychological: The irregular bleeding may become disconcerting and possibly discourage sexual intercourse.
- Headache and acne are commonly reported side effects.
- Interactions with other medications may make Implanon less effective. These medications include barbiturates, griseofulvin, rifampin, phenylbutazone, carbamazepine, felbamate, oxcarbazepine, topiramate, and modafinil. Herbal remedies such as St. John's wort may also reduce effectiveness. In these situations, a secondary nonhormonal method of birth control should be considered.

#### **PATIENT SELECTION**

The Implanon implant is particularly useful for women with contraindications to or severe side effects from estrogen. As previously mentioned, Implanon candidates would include those patients with a personal history of thrombosis, coronary artery disease, cerebrovascular disease, hypertension, or hepatic disorders. Included in this

**Figure 147-2** Implanon kit (see text for details). (Courtesy of Schering-Plough Corp., Kenilworth, NJ.)

list are those patients who suffer from other related estrogen side effects including migraine headaches, previous history of druginduced chloasma, and hypertriglyceridemia, and those women who are recently postpartum, breastfeeding, over the age of 35 years, or smokers. The published prescribing precautions are the same as for other progestin-only pills. Patients concerned about their fertility after discontinuation of Implanon should be counseled that they will experience a rapid return to baseline fertility, with over 94% of patients demonstrating ovulation within 3 to 6 weeks after removal of the implant. It is important to inform patients that irregular bleeding may be expected and might persist while the implant rod is in place. If the pattern of bleeding becomes intolerable, additional treatments can be employed to make the bleeding pattern more acceptable.

#### **PROCEDURE**

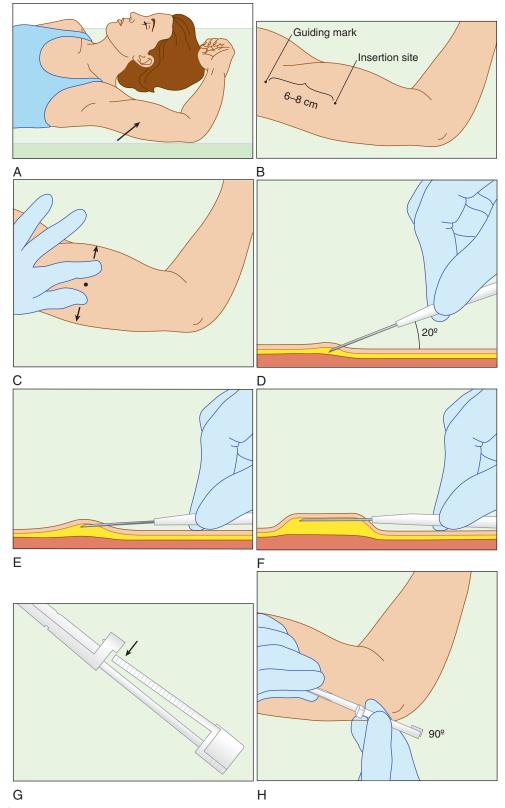

Ideally, the insertion should be scheduled within the first few days of a regular menstrual bleed, and the use of a "backup" method of birth control (i.e., condoms) should be recommended for 7 days after insertion.

The insertion procedure for Implanon is somewhat opposite that of an injection. The manufacturer has specific training seminars and onsite support available for health care providers wishing to offer this device to their patients. A provider must complete the manufacturer's course before being able to order Implanon and perform the procedure. This procedure is performed in the office setting. The Implanon rod and inserter should remain sterile throughout the procedure. If at any time sterility is compromised, a new device should be used.

#### **Insertion Technique**

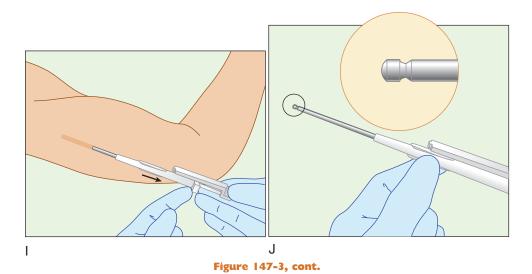

A video can be reviewed on the Implanon website, www. implanon-usa.com.

- 1. Have the patient lie on her back on the examination table with her nondominant arm flexed at the elbow and externally rotated. Her hand should be next to her head (Fig. 147-3A).
- 2. Mark a site for insertion 6 to 8 cm above the elbow crease on the nondominant arm. The site should be on the medial aspect of the arm, between the biceps and triceps. A second mark should be made on the same arm 6 to 8 cm *proximal* (farther up the arm) to the first mark (Fig. 147-3B).
- 3. Prep the insertion site with the antiseptic of choice.
- 4. Anesthetize the area locally with 1 to 3 mL of 1% to 2% lidocaine with or without epinephrine (see Chapter 4, Local Anesthesia).
- 5. Remove the inserter device (without the contraceptive rod in the needle/cannula) from the packaging.
- 6. Keeping the shield on the needle, identify the white rod inside the needle tip.
- 7. If not visible, tap the side of the device, with needle pointing down, to slide the rod into the needle tip.
- 8. Turn the needle up and shake or tap the rod back into the needle tip and remove the shield.
- 9. It is now possible for the rod to fall out of the needle. Keep the applicator in the upright position until insertion to minimize this risk.
- While applying countertraction to the skin (Fig. 147-3C), insert the tip of the needle bevel up into the skin. The angle of insertion should be less than 20 degrees (Fig. 147-3D).
- 11. Put the applicator in a position horizontal to the skin and lift the skin up with the tip of the needle keeping the needle sub-dermal (Fig. 147-3E).
- 12. Tent the skin and insert the needle fully into the subdermal tissue, aiming for the second mark made earlier on the arm (Fig. 147-3F).

**Figure 147-3 A–J, Insertion procedure (see text for details).** (Courtesy of Schering-Plough Corp., Kenilworth, NJ.)

Figure continues on following page.

- 13. Break the applicator seal by pressing the support for the obturator. Turn the obturator 90 degrees in either direction (Fig.
- 14. Hold the obturator in place on the arm and retract the cannula. Do not push or pull on the obturator. Slide the cannula off the device, allowing the insert to "fall in place" and be implanted in the patient (Fig. 147-31).
- 15. Confirm placement of the device. Check the needle to make sure the device is not in it. The grooved tip of the applicator should now be visible (Fig. 147-3]). Palpate the skin to feel the device in the proper location. If a rod cannot be palpated, it can be seen on ultrasound or magnetic resonance imaging (MRI). The rod cannot be seen on plain x-ray. An alternative form of contraception must be used until correct placement is verified.
- The wound can be dressed with an adhesive bandage and pressure dressing.
- 17. A card is provided to give to the patient with details of the device implanted.

#### Removal Technique

147-3G and H).

A video can be viewed on the Implanon website, www.implanon-usa.com.

- 1. Removal is performed with the patient in a position similar to that for insertion. The rod should be palpated or located with ultrasound prior to removal. The removal site should also be prepared with antiseptic solution.
- Locally anesthetize the area for removal, including the area under the rod (see Chapter 4, Local Anesthesia).
- 3. Make a 2- to 3-mm incision longitudinally at the end of the rod closest to the elbow using a no. 11 blade.
- 4. Push the rod toward the incision until it is visible. It may be necessary to further dissect the tissue to visualize the device.
- 5. Grasp the device with a hemostat and remove (Fig. 147-4A).
- 6. If unable to see the device, it may be grasped with one fine hemostat through the skin and further dissected with a second fine hemostat to facilitate removal (Fig. 147-4B). The fascia over the capsule may need to be incised with scissors or the no. 11 blade (Fig. 147-4C).
- 7. Ensure that the entire device has been removed by measuring it (length is 4 cm).
- A new device may be inserted into the same incision or the opposite arm if desired.
- 9. Dress the wound with an adhesive bandage and pressure dressing.

#### SAMPLE OPERATIVE REPORT

Preoperative diagnosis: Elective contraception with implantable device

Postoperative diagnosis: Same

Procedure performed: Insertion of Implanon contraceptive device

Surgeon: Dr. \_\_\_\_\_

Blood loss: None Complications: None

Procedure: The patient was placed in the supine position with her left arm up above her head exposing the medial (inside) portion of the upper left arm. The region above the antecubital space was prepped and draped. Local infiltration of the skin with 2 to 4 mL of 1% lidocaine with epinephrine was accomplished along a 3- to 4-cm line approximately 2 fingerbreadths from the antecubital space using a 27-gauge needle, and satisfactory anesthetic effect was achieved. A small vertical incision was made into the skin. The 19-gauge preloaded insertion cannula was directed at a 20-degree angle, beveled side up, through the incision and into the subcutaneous tissue, tenting up the skin to keep the needle just under the skin. The inserter cannula was stabilized and the Implanon implant passed down the cannula sleeve and deposited into the subcutaneous space. The inserter cannula was removed after the terminal ends of the deposited implant were palpated to confirm accurate placement within the designated tissue space. The skin incision was then closed with Steri-Strips (or adhesive bandage) and a small sterile pressure dressing was applied. Patient tolerated the insertion procedure well and will return to the office for follow-up in 3 days.

#### **COMMON ERRORS**

- Shallow insertion, causing the implant to be clearly visible directly under the skin surface.
- More commonly, the implant is inserted too deeply, which will make it difficult to palpate and complicate the removal process.
- Inadvertent removal of the obturator portion of the cannula results in the inability to advance the implant device.
- Inability to confirm proper placement of the Implanon device by digital palpation after the procedure may be due to placing the rod too deep in the fatty tissue (as noted earlier). Confirmation of correct placement should be attained by ultrasound or MRI. The patient must use a barrier method of contraception until proper placement is confirmed. Document this activity at the end of the operative report and in the patient's chart.

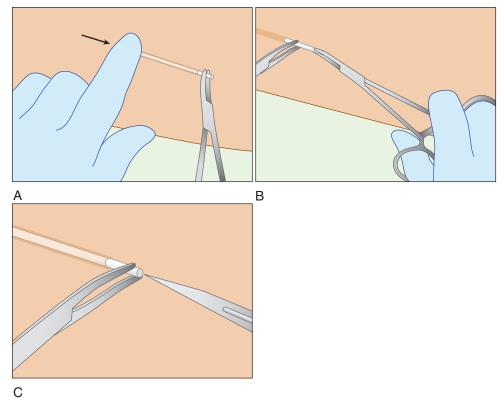

Figure 147-4 A-C, Removal procedure (see text for details). (Courtesy of Schering-Plough Corp., Kenilworth, NJ.)

#### **COMPLICATIONS**

- Postprocedure pain (insertion area of arm)
  - Determine if there is evidence of local nerve damage (extremely rare and unlikely).
  - Ecchymosis: confirm bandage is not applied too tightly. Apply ice packs for 24 hours.
  - Recommend NSAIDs or acetaminophen as needed.
- Infection in the insertion area
  - No abscess present. Suspect a localized cellulitis. Do not remove the rod. Clean the infected area with antiseptic solution and begin an oral antibiotic for 7 days. Evaluate in 24 hours and again after course of antibiotics is concluded.
  - Abscess is present. Begin course of antibiotics for 7 to 10 days.
     Prepare infected area, incise and drain any purulent material, and remove the rod. Drain and dress the wound and continue antibiotic therapy and wound care until resolved.

#### POSTPROCEDURE MANAGEMENT

- After insertion, apply a pressure dressing on the insertion site for 24 hours; thereafter, apply just a small bandage for approximately 3 to 5 days.
- After removal, Steri-Strips should be left in place until they "fall off." The wound should be treated as a simple laceration.

#### POSTPROCEDURE PATIENT EDUCATION

The process of wound healing should be discussed with the patient, and she should be reminded that the device does not protect against sexually transmitted diseases. The Implanon website has downloadable patient education materials available (www.implanon-usa.com).

# INSERTION OF ESSURE (HYSTEROSCOPICALLY ASSISTED FEMALE STERILIZATION)

Stephen A. Grochmal • Lydia A. Watson • Dale A. Patterson

Female tubal sterilization remains the most widely utilized method of permanent contraception worldwide. Approximately 700,000 female sterilizations are performed annually, and about of half of these are completed within 48 hours post partum. The remaining 345,000 sterilizations are "interval" procedures, meaning they do not occur immediately following pregnancy. Until recently, the majority of interval sterilization procedures in the United States were performed laparoscopically, under general anesthesia or intravenous (IV) conscious sedation, in either the hospital or an out-patient surgery setting. Although the laparoscopic approach is considered safe and effective, it is not without complications, including infection, anesthesia complications, vascular damage, failure, and injury to internal organs; and occasionally, as a result of a failed laparoscopic attempt, an unintended laparotomy may occur. Annually, an average of 14 women die in the United States from complications of tubal ligation surgery, and there is a reported 1/200 failure rate. Sterilization rates have remained the same for men and women over the past 45 years; however, the types of surgical procedures utilized have changed, influenced by improvements in medical device technologies and anesthesia.

Historically, the concept of hysteroscopic or transcervical occlusion of the fallopian tubes (using electrocoagulation) was first described by Schroeder in 1927. Unfortunately, there was sporadic interest in this hysteroscopic "scarless" tubal ligation procedure and further progress to find an acceptable method was plagued by numerous attempts and failures. An innovative technology was approved by the Food and Drug Administration (FDA) in November 2002 as the first hysteroscopic tubal occlusion device for permanent female sterilization in the United States. Now in its third generation, the Essure (ESS305, Conceptus, Inc., Mountain View, CA) is a less invasive, incisionless alternative to tubal ligation that provides significant advantages, such as decreased morbidity, rapid patient recovery, ability to detect failures, decreased expense, and a high level of patient satisfaction, when compared to tubal ligation.

Transcervical sterilization lends itself nicely to the office setting because it can be performed with little to no anesthesia or sedation in a standard gynecologic examination room. Patients describe only minimal postoperative discomfort and have a high tolerance for the procedure. A recent survey reported that more than 97% of patients who underwent the procedure would recommend it to a friend. Now, more than 8 years after its introduction, transcervical hysteroscopic sterilization (Essure) has proven to be an enduring technology, making hysteroscopic tubal occlusion increasingly popular as the option of choice for permanent interval female sterilization.

An investigation of the trends in female sterilization between January 1, 2002, and December 31, 2007, at the Detroit Medical

Center, Michigan, revealed a significant decrease in the percentage of interval laparoscopic sterilizations and postpartum tubal ligations performed after vaginal delivery. Of the interval sterilizations performed, the percentage of hysteroscopic sterilizations (Essure) increased significantly from 0% to 51.3% of all procedures performed. Although not indicative of a universal shift in trends across the United States, this study suggests that a minimally invasive, incisionless procedure is an appealing alternative choice for many patients.

The transcervical hysteroscopic sterilization procedure (Essure) entails one office visit, followed by a postprocedure low-pressure hysterosalpingogram (HSG) 3 months later. (See sample Essure confirmation test checklist online at www.expertconsult.com.) The placement of the Essure microinserts can be accomplished in about 9 minutes with a 97% to 99% successful bilateral placement rate with little to no patient discomfort and downtime.

If the physician is proficient with basic diagnostic office hysteroscopy, then performing the Essure procedure (after attending a certified device user course) would be a logical "next step" office procedure. Presently, many gynecologists and a few primary care physicians perform hysteroscopic sterilizations. Increased awareness and available training for hysteroscopic sterilization for "seasoned" practitioners or recent residency graduates will increase the popularity and availability of this permanent contraception option to patients.

A second method of transcervical sterilization has also become available. In July 2009, the Adiana Permanent Contraception System (Hologic, Inc., Bedford, MA) received FDA approval in the United States. Under hysteroscopic guidance, a catheter is introduced into the tubal ostium. Once correct placement inside the intramural portion of the fallopian tube is confirmed, a radiofrequency (RF) energy burst lasting for 1 minute produces a 5-mm lesion within the fallopian tube. Following this thermal injury, a 3.5-mm silicone matrix "plug" is deployed into this thermal lesion. During the next several weeks after the procedure, tubal occlusion occurs from in-growth of fibroblasts within the matrix, which acts like a permanent scaffolding permitting a "space-filling" effect to develop. Like the Essure procedure, confirmed tubal occlusion must be assessed by hysterosalpingogram in 3 months after the device has been placed.

Presently, experience with the Adiana system in the United States is limited. The cumulative available worldwide data cover up to 3 years; however, the data from the pivotal trial provide important clinical information. Additional information for the reader can be found at the end of this chapter. Although appropriate to highlight new, emerging technologies and treatment

**Figure 148-1** Essure microinsert. (Courtesy of Conceptus, Inc., Mountain View, CA.)

options, our discussion in this chapter will focus only on the Essure procedure.

#### **ANATOMY**

The anatomy relevant to Essure placement is identical to that described in Chapter 140, Hysteroscopy.

#### **INDICATION**

Hysteroscopic sterilization is indicated for any woman who desires permanent elective sterilization.

#### **CONTRAINDICATIONS**

#### **Absolute**

- Pregnancy or suspected pregnancy
- Less than 6 weeks after delivery or abortion
- Inability to observe both tubal ostia during hysteroscopy
- Patients who have previously undergone a tubal ligation
- Nickel allergy (documented by skin testing)

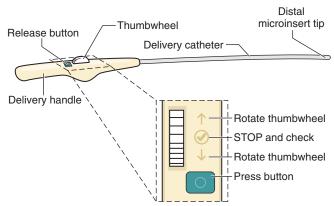

#### Relative

- Radiologic contrast allergy
- Active or recent pelvic infection
- Uterine anomalies
- Immunosuppressive therapy

#### **EQUIPMENT AND SUPPLIES**

- Materials for a paracervical block (see Chapter 173, Paracervical Block)
- Powered examination table
- The standard hysteroscopic equipment already available in the physician's office (see Chapter 140, Hysteroscopy)

The third generation Essure system (ESS305) consists of two Essure microinserts (Fig. 148-1) (one insert per disposable delivery catheter) and two disposable introducers (Fig. 148-2). A standard hysteroscope with a 5 French operating channel, preferably with continuous flow and an angle of view between 12 and 30 degrees is

**Figure 148-2 Delivery system.** (Redrawn from images courtesy of Conceptus, Inc., Mountain View, CA.)

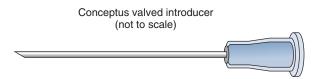

required equipment necessary for this procedure. The only uterine distention medium recommended for hysteroscopic sterilization is normal saline using a gravity flow system (see Chapter 140, Hysteroscopy).

The Essure microinsert (see Fig. 148-1) consists of two coils composed of a flexible stainless steel inner coil and an outer coil made of nickel-titanium alloy (nitinol) and polyethylene terephthalate (PET) fibers. The insert measures 3.85 cm in length and 0.8 mm in diameter in the "wound down" or contracted configuration. The microinserts do not contain or release hormones. Once inserted, the PET fibers stimulate a local, benign tissue growth that surrounds and infiltrates the device over the course of several weeks, leading to occlusion of the tubal lumen.

The disposable *delivery device handle* contains a delivery wire, release catheter, and delivery catheter housing the microinsert. An ergonomic, single-use handle provides effortless control of the microinsert deployment via a button-thumbwheel combination built in to the handle (see Fig. 148-2). The valved, DryFlow introducer permits passage of the Essure introducer catheter into the operating channel without any valve manipulation on the hysteroscope, thus preventing backflow of fluid. The ESS305 has a new gold band where the notch used to be on the previous version, making it easier to visualize and correctly place the device into the tubal ostia. The release catheter has a contrasting green color to improve visibility. Also, the device has an automatic release mechanism on the handle that eliminates the need, as was required with the previous generation, for counterclockwise rotations to disconnect the introducer catheter from the actual implanted insert (Fig. 148-3).

#### **PRECAUTIONS**

- Patient must use an alternative form of contraception until an HSG is done to confirm both placement and tubal occlusion.
- Essure does not prevent sexually transmitted diseases.
- Essure is considered permanent and irreversible.
- Caution should be used when performing surgeries with electrosurgical or radiofrequency devices in the pelvis because Essure microinserts may conduct energy and potentially injure the patient.
- If both tubal ostia cannot be visualized, the procedure cannot be performed.
- If patient has a known prior history of intrauterine disease, previous surgical procedure, or uterine anomaly, consideration should be given to performing a "presterilization" diagnostic hysteroscopy to rule out any abnormal uterine conditions prior to the day of the planned hysteroscopic sterilization.
- The presence of an intracavitary lesion may obstruct the view of the tubal ostia and the Essure procedure may be technically difficult to perform. Removal of the lesion (e.g., submucous fibroid, endometrial polyp) may be necessary before the Essure microinserts can be placed.

**Figure 148-3** Valved DryFlow introducer for the Essure ESS305. (Redrawn from images courtesy of Conceptus, Inc., Mountain View, CA.)

#### PREPROCEDURE PATIENT EDUCATION

Presurgical counseling is important. The patient should understand that she is contemplating a permanent procedure. This is particularly important in young patients, who may later regret their decision to be sterilized. A history of nickel allergy should be elicited in preprocedure discussion. Patients with a possible nickel allergy must undergo specific allergy testing prior to the procedure. Patients should also be queried about an allergy to contrast dye because the HSG is still required postprocedurally by the FDA protocol. If an allergy exists to dye, ultrasound is a useful alternative and is equally effective at confirming tubal occlusion; however, the patient must be told that the postprocedure evaluation of her fallopian tubes will be a deviation from the recommended FDA protocol.

It is important to schedule the patient during the early proliferative phase of her cycle. If needed, medical preparation of the endometrium with low-dose oral contraceptives or norethindrone (5 mg) or medroxyprogesterone (10 mg) can begin around day 4 or 5 of the cycle and continue until the procedure date. This helps prevent menstruation and produces a temporary atrophy of the uterine endometrium, which aids in improving visualization and manipulation within the uterine cavity during the hysteroscopic procedure. Hysteroscopic sterilization may be successfully performed in patients with a Mirena IUD in place within the uterine cavity. The IUD's presence may be advantageous by allowing more flexibility in the timing of the Essure procedure, providing continuous contraceptive effect until confirmation of tubal occlusion at 12 weeks.

The risks of hysteroscopy (see Chapter 140, Hysteroscopy), including an unlikely but small risk of tubal perforation, should also be discussed with the patient. The sterilization procedure is 99.74% effective in preventing pregnancy after 5 years of follow-up. It should again be emphasized that a backup birth control method must be used until bilateral tubal occlusion and correct placement are confirmed by HSG. (See sample consent form online at www. expertconsult.com.)

#### **PROCEDURE**

Figure 148-4 illustrates the insertion procedure. Because the procedure is short, there is no need for conscious sedation or general anesthesia. A paracervical block (see Chapter 173, Paracervical Block) along with nonsteroidal premedication (recommended to prevent tubal spasm) is all that is needed to keep the patient comfortable during the procedure. The average office visit time "start to finish" is approximately 30 minutes with just about 9 to 10 minutes of actual hysteroscopy time to place the microinserts.

- 1–8. The procedure begins with insertion of the hysteroscope (steps 1–8 are identical to the procedure described in Chapter 140, Hysteroscopy). Once both tubal ostia have been identified, the insertion procedure begins as outlined in Figure 148-4.
- Identify both tubal ostia and ensure that they are normal in appearance.

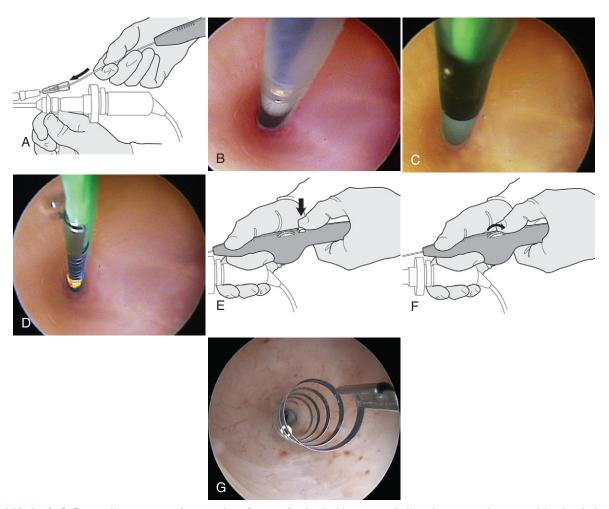

Figure 148-4 A-G, Essure placement steps for procedure. See text for details. Note especially how the inserter device is stabilized with the hand on the hysteroscope.

- 10. Insert the introducer through the working channel of the hysteroscope (see Fig. 148-4A).
- 11. Advance the catheter through the introducer to the tubal ostium on one side. There is a black marker on the introducer to signify the correct location of the catheter at the ostium (see Fig. 148-4B).
- 12. Stabilize the device handle on the hysteroscope.
- 13. Roll the thumbwheel on the inserter handle back so that the black positioning marker on the catheter moves toward you until reaching a hard stop. The handle is marked with a "1" and an arrow at this location (see Fig. 148-4C).
- 14. Check the placement of the microinsert by locating the gold band, which should be just outside the ostium with the green release catheter in view (see Fig. 148-4D).
- 15. Deploy the insert by pressing the button on the handle. The microinsert will not yet expand, allowing for any final positioning adjustments for the insert at this time (see Fig. 148-4E).
- 16. Expand and detach the microinsert by rolling the thumbwheel back to a second hard stop (see Fig. 148-4F).
- 17. Document visualization of the coils at the ostium to show proper placement (see Fig. 148-4G).
- 18. Withdraw the catheter, leaving the introducer in place.
- 19. Insert another catheter into the hysteroscope and repeat steps 11 to 18 on the other tubal ostium.
- 20. Remove the introducer. Then remove the hysteroscope from the uterine cavity under direct visualization.

When inserted, the device is placed in the proximal fallopian tube in the contracted state (Fig. 148-5A) and then deployed to an expanded state once correctly positioned in the interstitial portion of the tubal lumen. After release, the outer coil expands to 1.5 to 2.0 mm in diameter, anchoring and embedding the microinsert in each fallopian tube (Fig. 148-5B).

The trailing coils of the microinsert are easily visualized at each tubal ostium, ensuring "on-site" confirmation of proper placement within the fallopian tubes. Once the inserts are in place, the PET fibers elicit tissue in-growth. The PET fiber mesh and the microinsert act as scaffolding into which the tissue grows, further embedding the microinsert within the proximal uterotubal junction, thus resulting in sterilization (Fig. 148-5C). Correct placement of the radiopaque microinserts and tubal occlusion is confirmed by HSG 12 weeks following the procedure (Fig. 148-5D).

#### SAMPLE OPERATIVE REPORT

Identifying data: Patient is a 36-year-old white G2P2 who requests sterilization by Essure micoinserts

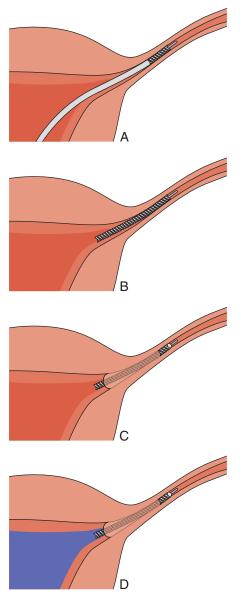

Preoperative diagnosis: Elective permanent sterilization Postoperative diagnosis: Bilateral Essure insertion

Estimated blood loss: None Complications: None

Operation performed: Hysteroscopically guided bilateral tubal sterilization with Essure microinserts

Surgeon: Dr. \_\_\_\_\_ Anesthesia: Paracervical block

Procedure: The patient's preoperative examination and consent were obtained with a prior office visit. A negative urine pregnancy test was confirmed prior to starting the procedure. The patient was placed in the dorsolithotomy position and a bimanual examination demonstrated a normal-sized, mobile uterus without abnormality. An open-sided self-illuminating speculum was inserted into the vagina and the cervix identified and prepped with antiseptic solution. A paracervical block was performed with approximately 5 mL of 1% lidocaine. The anterior lip of the cervix was grasped with a single-tooth tenaculum. The cervix was progressively dilated to approximately 6 mm. The hysteroscope was inserted under direct visualization into the uterine cavity. The uterine cavity was distended with normal saline via a gravity

**Figure 148-5** Essure procedure for permanent birth control. **A**, Using a hysteroscope, the Essure microinsert is inserted into the fallopian tube using a small catheter. **B**, Once deployed, the Essure microinserts expand to fit the fallopian tube, which anchors them in place. **C**, After approximately 12 weeks after procedure, tissue grows into the Essure microinserts, forming a permanent natural barrier, which occludes the fallopian tube. **D**, At 3 months, low-pressure hysterosalpingography is performed. The radiologic study documents that injected dye remains in the uterine cavity and does not pass through the fallopian tubes, confirming tubal occlusion. (Courtesy of Conceptus, Inc., Mountain View, CA.)

flow system. The uterine fundus was well visualized. Both tubal ostia were identified and appeared normal. The tip of the hysteroscope was brought within close proximity of the patient's left tubal ostium. The Essure microinsert was advanced through the operating channel of the hysteroscope and maneuvered easily into the left fallopian tube. Under direct visualization, the microinsert was deployed without difficulty. After release, the trailing coils of the microinsert were easily visualized at the tubal ostium. The preceding technique was repeated, resulting in a successful, confirmed placement of a microinsert into the patient's right fallopian tube. The hysteroscope was withdrawn under direct visualization. All instrumentation was removed from the vagina. The patient tolerated the procedure well.

#### **COMMON ERRORS**

- Performing sterilization on a patient who is uncertain about future childbearing. Be certain to discuss the permanent nature of the procedure.
- Failure to obtain HSG 12 weeks after the procedure. Be certain
  to arrange follow-up for this portion of the procedure to ensure
  efficacy and proper placement. Alternatively, ultrasonography
  (two or three dimensional) can be utilized to determine successful bilateral placement because the microinserts are highly echogenic on pelvic ultrasound.
- Failure of physician to properly reinforce patient compliance regarding the importance of back-up contraception until the HSG confirms both correct placement and tubal occlusion. Should the HSG be inconclusive, the patient must continue back-up contraception until a final determination is reached.
- Microinsert removal should not be attempted hysteroscopically once the microinsert has been placed and detached from the delivery wire. Attempted removal of a microinsert having less than 18 coils trailing into the uterine cavity may result in tubal perforation or other patient injury. Consult product Information for Users guide (IFU) for complete details and exceptions.

#### **COMPLICATIONS**

Failure rates. Evaluation of all available clinical data from 2001 to 2009 reveals 503 reported pregnancies with 372,112 Essure systems sold commercially. Most pregnancies are avoidable and occur as a result of physician/patient noncompliance with recommended follow-up or misinterpreted confirmation test.

Although no major complications are associated with transcervical sterilization, *short-term complications* reported in the IFU or recent clinical studies include the following:

- Inability to place two microinserts in the first procedure, ~3.1% (Levie, 2009).
- An initial tubal patentcy rate of 3.5% at 3 months and 0% at 6 months.
- Expulsion rate of 2.9%.
- Unsatisfactory device location, 0.6%.
- Risks related to the insertion procedure itself include cramping (29.6%) and pain (12.9%) on the day of the procedure, dizziness (8.8%), bleeding or spotting (6.8%), vasovagal response/fainting (1.3%). The majority of patients actually consider the procedure painless or scarcely painful. Cramping pain during the procedure was reported comparable to or less than menses.
- Tubal perforation rate of 1.1%. Tubal perforation may often go undiagnosed during the procedure or even at the HSG 3 months after the sterilization. The microinsert may perforate into the peritoneal cavity and be entrapped by the omentum causing chronic pain or can lead to complications such as hemorrhage, infection, or bowel injuries and compromise the contraceptive efficiency of Essure (Fig. 148-6). Therefore, in the case of a suspected perforation into the abdominal cavity, the prudent option is to investigate sooner rather than later. The possible need for a laparoscopic evaluation (carried out elsewhere if procedure is office-based) should always be discussed prior to the procedure as part of the informed consent. Alternatively, the use of fluoroscopy and two- or three-dimensional ultrasound have been suggested as useful tools in locating microinserts dislodged into the abdominal cavity

#### POSTPROCEDURE MANAGEMENT

- Patients return to work in 1 day and most resume their daily activities the same day as the procedure.
- Patients should be counseled to use an alternative form of contraception until HSG confirmation of placement and occlusion of tubal lumen.

**Figure 148-6** Perforation by Essure microinsert of left side of the proximal tube. The microinsert remains attached to the tube by its distal portion while the proximal end rests on the fatty tissue of the sigmoid colon. (Courtesy of V. Thoma, MD.)

 Patients should be educated to inform their health care providers of the presence of Essure microinserts prior to undergoing any future medical or surgical procedure.

### Concomitant Hysteroscopic Sterilization and Global Endometrial Ablation

Initially, FDA approval was granted for a Thermachoice endometrial ablation (see Chapter 156, Endometrial Ablation) to be performed concomitantly on those women who had a transcervical microinsert hysteroscopic sterilization. After evaluation of postapproval study data, the FDA later recommended a modification to the microinsert procedure label stating that the Thermachoice treatment should not be performed until after the completion of the 3-month HSG.

Until recently, little was known about concomitant use of global endometrial ablation (GEA) methods for endometrial ablation (e.g., balloon, cryoablation, hydrothermablation [HTA] microwave or RF energy) and hysteroscopic sterilization with microinserts. Studies assessing Thermachoice and Essure in a perihysterectomy setting demonstrated no interference with achieving a uniform ablation effect and no conduction of heat via the Essure microinsert to the serosal surface of either fallopian tube or cornua. Another retrospective study of concomitant use of Thermachoice, NovaSure, and HTA demonstrated an 85% patient satisfaction rate and no adverse events leading to the conclusion that performance of combined GEA and hysteroscopic sterilization is effective in the treatment of menometrorrhagia.

Although current data support that it is feasible and effective to perform GEA and hysteroscopic sterilization at the same session, long-term data are still needed. Either the Essure or ablation can be performed first, depending on the topography of the uterine cavity, surgeon's expertise, and the type of energy utilized for the ablation.

- Remember that, if a concomitant procedure is planned, you must inform the patient that this is an off-label, non-FDA approved use of these combined technologies.
- It would be prudent that, taking into consideration all of the preceding information, until a level of proficiency is reached with office hysteroscopic sterilization, any endeavor to perform a concomitant procedure should be carried out with particular caution.

#### **CPT/BILLING CODES**

Physician reimbursement for this procedure is substantially greater if the procedure is performed in the office rather than the hospital.

58340 Catheterization and introduction of saline or contrast material for saline infusion sonohysterography or hysterosalpingography

58565 Hysteroscopy, with bilateral fallopian tube cannulation to induce occulsion by placement of permanent implants

#### **ICD-9-CM CODES**

V25.09 Family planning advice

V25.2 Sterilization, admission for interruption of fallopian tubes/

V25.40 Contraceptive surveillance, unspecified

#### **ACKNOWLEDGMENT**

The authors wish to thank Jeanne Ballard, MD, for her assistance with this chapter.

# LOOP ELECTROSURGICAL EXCISION PROCEDURE FOR TREATING CERVICAL INTRAEPITHELIAL NEOPLASIA

Thomas C. Wright, Ir.

A variety of techniques can be used to treat cervical intraepithelial neoplasia (CIN). The appropriateness of a particular technique to treat a particular lesion depends on a number of factors, including lesion size, location, and extension into the endocervical canal. Many clinicians now use the loop electrosurgical excision procedure (LEEP) to treat most women with biopsy-confirmed CIN 2 or CIN 3. With LEEP, thin wire loop electrodes are used to excise the entire cervical transformation zone. This procedure is referred to by a number of different names, including loop electrosurgical excision procedure (LEEP), large loop excision of the transformation zone (LLETZ), and loop excision. Many clinicians subdivide LEEP into two procedures: (1) routine LEEP, which is used to excise lesions confined to the exocervix (or visible portion of the cervix), and (2) LEEP conization, which is used when lesions extend into the endocervical canal. LEEP has a number of advantages over other treatment modalities for CIN, including the following:

- The equipment is less expensive than laser equipment.
- The entire lesion is excised and can be assessed histologically to rule out invasive cancer.
- Patients can be diagnosed and treated in a single office visit.
- It allows cervical conization to be performed in the office at a significantly reduced cost (LEEP conization).
- Complications are few for the procedure itself, but it can affect future pregnancies.

#### **ANATOMY**

The anatomy relevant to the LEEP is reviewed in detail in Chapter 137, Colposcopic Examination. As the procedure involves complete removal of the transformation zone, it is important to understand the anatomy of the cervix, including normal and abnormal appearances. In most circumstances, a colposcopy will be completed prior to the LEEP to define the anatomy of the cervix.

#### **INDICATIONS**

The following indications are based on the 2006 American Society for Colposcopy and Cervical Pathology (ASCCP) guidelines that are reproduced in Appendix K, Management Guidelines for Abnormal Cervical Cancer Screening Tests and Histologic Findings. Several options are given for treatment of most of these indications. This chapter presents the possible indications for the LEEP.

#### **Routine LEEP**

- Biopsy-confirmed CIN 2 or CIN 3 and a satisfactory colposcopy
- High-grade squamous intraepithelial lesion (HSIL) on referral cytologic examination that is immediately treated in a patient over age 20 ("screen and treat")
- Persistent HSIL on screening for 6 to 12 months (without CIN 2 or 3 documented by biopsy)
- CIN 1 on biopsy after screening result of HSIL or atypical glandular cells—not otherwise specified (AGC-NOS)

When several treatment options exist with the treatment guidelines, LEEP is preferred over ablative therapies such as cryotherapy in the following conditions:

- High-grade lesion involving three or more quadrants
- Complex-appearing CIN 2 or 3 with prominent abnormal vessels
- Lesion is not covered by cryoprobe
- Ectocervix is irregular
- Patients have recurrent CIN after previous therapy (e.g., cone biopsy, LEEP, cryotherapy)

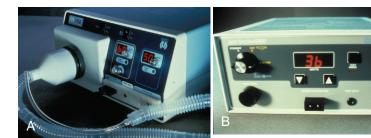

#### **LEEP Conization**

- Unsatisfactory colposcopy in women with biopsy-confirmed CIN of any grade (e.g., cannot see entire lesion, squamocolumnar junction [SCJ], or transformation zone [TZ])
- HSIL on referral cytologic examination and unsatisfactory colposcopy
- HSIL on referral cytologic examination with satisfactory colposcopy and either no CIN or only CIN I identified ("lack of correlation principle")
- Positive endocervical sampling (e.g., neoplasia of any grade present)
- Microinvasive lesions on cervical biopsy

#### **CONTRAINDICATIONS**

#### Relative

- Bleeding diathesis
- Patient exposed in utero to diethylstilbestrol
- Patient fewer than 12 weeks after delivery
- · Equivocal cervical abnormalities
- Heavy menses

- A preexisting short cervix (clinician should consider referral)
- Patients with pacemakers (special precaution necessary)
- Severe cervicitis

#### Absolute

- Pregnancy
- Clinically apparent invasive carcinoma of the cervix
- Lack of expertise to control potential severe cervical bleeding

#### **EQUIPMENT AND SUPPLIES**

- Electrosurgical generator or unit (ESU) (Fig. 149-1) with the following features:
  - Minimum output capability of 50 watts in both cutting and coagulation modes
  - Rapid-start features
  - Patient grounding pad monitor (beneficial if the patient is under anesthesia)
  - Isolated circuitry

**EDITOR'S NOTE:** Although the Ellman Surgitron does not meet some of these qualifications, it has been used extensively for the LEEP.

 Loop electrodes of the appropriate size and a ball electrode for fulguration (Fig. 149-2). (These electrodes can be either of the disposable or of the reusable variety.)

It is recommended that clinicians use only the shallow loop electrodes (i.e., either 0.8 or 1.0 cm deep) for routine LEEP. Larger electrodes can be used with large cervices or when lesions extend into the endocervical canal (e.g., LEEP conization). A variation is the Fischer electrode, which provides a true "cone" specimen.

- Electrode handle and a patient return electrode (grounding pad or antenna).
- Nonconductive speculum (either coated with a nonconductive material or made of plastic) capable of being used in conjunction with a smoke evacuator (Fig. 149-3).
- Smoke evacuator equipped with an adequate viral and odor filter.
- Colposcope capable of low magnification (4x to 7.5x).
- Nonsterile gloves.
- Acetic acid (5%).
- Full-strength aqueous Lugol's solution.

C

- Cotton balls and large OB-GYN applicators.
- Ring forceps.
- Syringe (5 mL) with 4-inch needle extender and 1½-inch, 25-gauge needle as well as 5 mL of 2% lidocaine with epinephrine, or dental type of syringe equipped with a 25- to 27-gauge needle at least 1½ inches long with two 1.8-mL ampules of 2% lidocaine with 1:100,000 epinephrine (Fig. 149-4).
- Coated vaginal sidewall retractor (arrow, see Fig. 149-3).
- Kevorkian endocervical curette.
- Monsel's paste, which is made by allowing Monsel's solution to evaporate until it forms a thick yellow paste.
- Containers of histologic fixative (usually 10% formalin).
- A 12-inch needle holder and 2-0 Vicryl suture material together with a vaginal pack in the event that large-vessel bleeding occurs.
- Power examination table with adjustable height (recommended).

#### **PRECAUTIONS**

It is imperative that the LEEP not be used to excise the TZ indiscriminately in women with atypical Papanicolaou (Pap) smears. The procedure should be reserved to treat advanced lesions as per the established indications, not just atypical Pap smears or CIN 1. CIN 1 has a high rate of regression and should usually be observed or

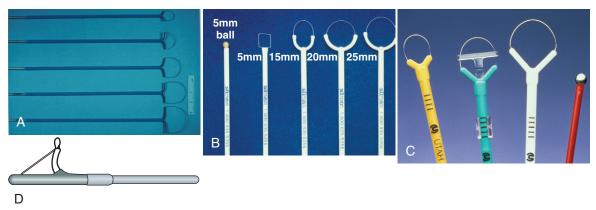

Figure 149-2 Wire loop electrodes for loop electrosurgical excision procedure (LEEP). **A,** Loop electrodes come in a variety of sizes and shapes. **B,** Ellman electrodes. **C,** Utah Medical electrodes with an optional adjustable stop to limit depth (*middle*, green-handled loop). **D,** Fischer electrode, which removes more of a conical piece. (**A–C,** Courtesy of The Medical Procedures Center, PC, John L. Pfenninger, MD.)

**Figure 149-3** Coated instruments to prevent electrical shocks. Vaginal sidewall retractors (*arrow*) are essential in many cases to avoid lacerating the vaginal walls. Three different vaginal speculums are on the left, each with a vented tube to attach to the smoke evacuator tubing.

treated with less invasive options. Cryotherapy is less expensive, has fewer complications, and has equal outcomes in properly selected patients (while at the same time removing less tissue) (see Chapter 138, Cryotherapy of the Cervix). Cold-knife conization is preferred when conization is being performed for a glandular abnormality.

#### PREPROCEDURE PATIENT EDUCATION

- Provide a patient education handout (see the sample patient education handout online at www.expertconsult.com).
- Instruct the patient to take 600 to 800 mg of ibuprofen or a preferred nonsteriodal anti-inflammatory drug 1 to 2 hours before the procedure.
- Obtain informed consent.

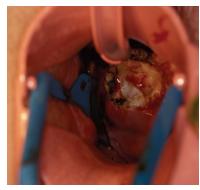

#### **PROCEDURE**

The procedure is best performed immediately after menses so that any vaginal bleeding is not confused with menses.

- Have the patient undress from the waist down and lie on the gynecologic examination table. It is important that the patient not move, cough, or change position once the excision is started. Thus, a cooperative patient is essential.
- 2. Attach the patient return electrode grounding pad to the patient's thigh and connect the grounding pad to the ESU (or place the "antenna plate" under the hip).
- 3. Insert a nonconductive speculum with the smoke evacuator attachment into the vagina and connect it to the smoke evacuator. It is important that the speculum be large enough to allow complete, unobstructed visualization of the cervix. If the vaginal sidewalls remain in the way, use a vaginal sidewall retractor (Fig. 149-5, and see Fig. 149-3).
- 4. Apply the acetic acid solution, examine the cervix colposcopically, and identify all lesions and the TZ.
- Apply full-strength Lugol's solution to the cervix (this lasts longer than acetic acid). Use cotton balls or a large OB-GYN applicator.

Figure 149-4 A, Needle extender (5 inch). B, Needle extender placed on the end of a 5-mL syringe with 25-gauge, 1½-inch needle attached. (Courtesy of The Medical Procedures Center, PC, John L. Pfenninger, MD.)

**Figure 149-5** The cervix as seen through a coated vaginal speculum with coated, nonconductive sidewall retractors in place.

- 6. Inject approximately 0.5 to 1.5 mL of 2% lidocaine with epinephrine 1:100,000 intracervically (submucosally) at each of the 12, 3, 6, and 9 o'clock positions (to a total of 2 to 6 mL), usually just outside the TZ. Take care to inject the cervix superficially, only 3 to 5 mm deep. Additional injections may be needed at intervals between those noted previously, depending on the size of the cervix.
- 7. Although loops of many different sizes are available from various manufacturers, a round loop 2 cm wide by 0.8 cm deep (R2008) is most frequently used for CIN lesions confined to the portio. For a small, nulliparous cervix, use a 1.5 × 0.7 cm loop (R1507). For LEEP conizations when lesions extend into the endocervical canal, a 1 × 1 cm loop electrode can be used to excise the endocervical canal itself. This can be performed after the ectocervical excision has been completed to perform a "cowboy hat" type of procedure (see Fig. 149-7C).

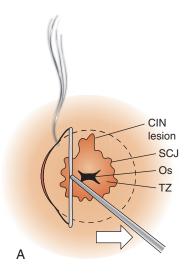

The power required will depend on the ESU used and the diameter of the loop. In general, a  $2.0 \times 0.8$  cm loop will require between 35 and 45 watts of power, whereas a  $1 \times 1$  cm loop will require only 20 to 30 watts of power. For LEEP, the use of a blended (cut and coagulate) current provides the combination of minimal tissue artifact and minimal amounts of bleeding. However, many use a *pure cutting* setting, which provides even less burn artifact for the pathologist while still controlling bleeding. It also allows for the use of less power so less tissue is damaged.

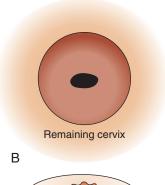

Three different types of cervical LEEP excisions can be performed, depending on the size and location of the CIN lesion: (1) LEEP for small lesions confined to the exocervix, (2) LEEP for large lesions confined to the ectocervix, and (3) LEEP conization for lesions extending into the endocervix.

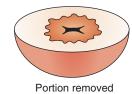

For small lesions confined to the ectocervix, the following is suggested:

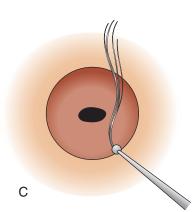

- Select a loop electrode 1.5 to 2.0 cm wide and 0.8 cm deep.
- Place the loop several millimeters lateral to the edge of the CIN lesion and make a test pass over the lesion to ensure that the path is clear.
- Hold the loop just above the surface, activate the loop, and then push it perpendicularly, gradually, into the tissue to a depth of about 4 mm.
- While pushing the loop deeper into the cervical stroma to the full depth of 8 mm, draw it laterally and through the endocervical canal. Pull it to the other side several millimeters past a lesion or several millimeters beyond the TZ, whichever is more lateral, before removing it (Fig. 149-6).

**NOTE:** In most instances the entire CIN lesion and the TZ can be removed in a single pass. This produces a donut-shaped specimen with the endocervical canal in the center.

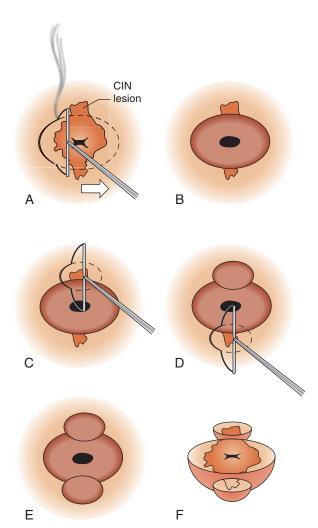

**Figure 149-6** Standard loop electrosurgical excision procedure (LEEP) for cervical intraepithelial lesions that can be removed in a single pass. After painting the cervix with Lugol's solution and injecting lidocaine, the clinician uses an ectocervical loop (2 cm wide and 0.8 cm deep) to resect the entire lesion (**A** and **B**). Then the crater base is coagulated using a 5-mm ball electrode followed by the application of Monsel's paste (**C**). CIN, cervical intraepithelial neoplasia; SCJ, squamocolumnar junction; TZ, transformation zone.

For larger lesions confined to the ectocervix, the following technique is advised:

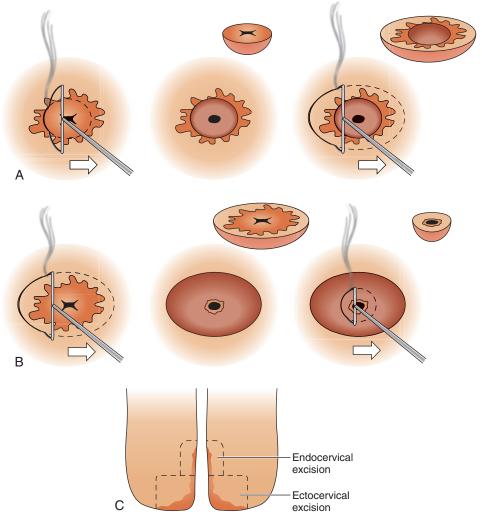

- In some instances, CIN lesions may be too extensive to be removed in a single pass. In this event, remove the central portion of the lesion using a 2-cm wide loop electrode, as previously described.
- Then, excise the remaining CIN and TZ with additional, more superficial passes using the same loop electrode. Alternatively, the remaining tissue can be ablated using electrocoagulation with a ball electrode (Fig. 149-7).

For CIN extending into the endocervical canal, LEEP conizations are performed and lesions are removed in a two-step procedure that uses a 2-cm wide exocervical electrode in conjunction with a  $1\times 1$  cm loop or square endocervical electrode to produce a cowboy-hat type of excision. For this procedure, one of two methods can be used:

• The *first method* involves excising the endocervical portion of the lesion first using the 1 × 1 cm endocervical electrode. Once the endocervical portion of the lesion is excised, the exocervical portion is excised using a standard 2.0 × 0.8 cm loop electrode (Fig. 149-8A).

**Figure 149-7** For lesions too large to be removed in a single pass, the clinician uses a  $2 \times 0.8$  cm loop electrode to resect the central portion of the lesion ( $\bf A$  and  $\bf B$ ). Then, the remaining tissue is resected with additional passes using the same electrode ( $\bf C-E$ ). Tissue specimens ( $\bf F$ ) are placed in the same bottle of formalin. CIN, cervical intraepithelial neoplasia.

**Figure 149-8** Two methods for obtaining an endocervical sample with the loop electrosurgical excision procedure:  $\bf A$ , The clinician resects the endocervical portion of the lesion using a  $1 \times 1$  cm loop. Then a  $2.0 \times 0.8$  cm loop is used to resect additional cervical intraepithelial neoplasia extending onto the portio.  $\bf B$ , In some cases it may be necessary to excise the ectocervical portion first. Excising to a depth greater than 1.5 cm into the canal increases the chances of significant bleeding.  $\bf C$ , Longitudinal section showing the "cowboy-hat" procedure.

• In the second method, the large ectocervical portion is excised first, followed by the smaller endocervical portion (Fig. 149-8B). Care should be taken not to excise the endocervical canal too deeply. Both approaches leave a cowboy-hat shaped excision on the cervix (Fig. 149-8C). The endocervical and exocervical excisional specimens should be submitted for pathologic assessment in separate containers.

Some pathologists prefer that after the specimen is excised, it be removed from the cervix using forceps, opened along one side, and placed in a plastic holder to allow it to fix in formalin in the proper orientation. Other pathologists prefer the specimen to be tagged at a certain location. Clinicians should check with the particular pathologist to determine preferences. Generally "tagging" the tissue to provide location provides little practical information. Although some clinicians want to know whether or not the endocervical margin of the specimen is involved with CIN, this can be difficult to evaluate because of tissue orientation on the histology slide and thermal damage. An endocervical curettage (ECC) taken immediately after the LEEP can also be used to evaluate whether the CIN lesion has been removed in its entirety. In most instances when the margin or post-LEEP ECC is positive, the patient should simply be

- followed up 4 to 6 months later with cytologic examination and a repeat ECC (see Complications).
- 8. Inspect the ectocervix and the endocervical canal to ensure that all nonstained (iodine negative) ectocervix and all acetowhite epithelium (AWE) in the canal have been excised. (More acetic acid may need to be applied with a Q-Tip to the canal.) If AWE remains in the canal (often identified by a thin rim of white along the margin of the os), another excision should be carried out and the process repeated until there is no AWE remaining. Care should be taken not to interpret thermal cautery effect in the endocervical canal as residual neoplasia.
- 9. Perform an ECC above the excisional base. This helps confirm there was no dysplasia above the excision.
- 10. Fulgurate any bleeding points at the base of the excision using a ball electrode with the "coagulation" setting on the ESU. For 5-mm ball electrodes, power settings of 40 to 55 watts are usually required to obtain adequate arcing between the electrode and the tissue. (Excessive bleeding is more frequent in patients with severe cervicitis and in those less than 12 weeks after delivery.) Frequently the entire base of the excision is lightly coagulated. Perform the coagulation up to the endocervical canal, but take care not to insert the electrode into the

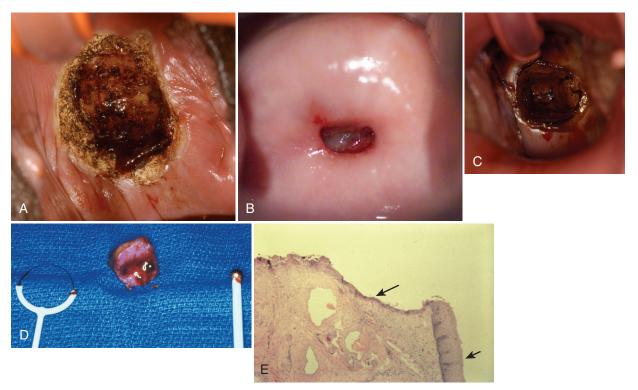

Figure 149-9 A, Appearance of the cervix as seen through a nonconductive speculum immediately after the loop electrosurgical excision procedure (LEEP). B, Appearance of cervix 4 months after LEEP. Note the absence of an ectocervical transformation zone. C, Appearance of cervix immediately after the "cowboy-hat" LEEP procedure (ectocervical and endocervical excision). Coated speculum and smoke evacuator tubing are in place. D, Tissue specimen from a single-pass LEEP procedure. E, Microscopic view of the removed tissue. Note the minimal tissue damage on the resected edge (arrows). (Courtesy of The Medical Procedures Center, PC, John L. Pfenninger, MD.)

canal. Excessive coagulation is not warranted and may be detrimental to optimal healing.

11. Apply Monsel's paste to the entire area. Figure 149-9A to E shows the typical cervix upon completion of the procedure with Monsel's applied (A) and 4 months after the procedure (B). Part C shows another cervix after the "cowboy hat" procedure as seen through a coated vaginal speculum. Part D shows the average tissue specimen from the LEEP. Part E is a microphotograph showing the minimal amount of thermal tissue damage from the LEEP.

#### SAMPLE OPERATIVE REPORT

Preoperative diagnosis: CIN 3 Postoperative diagnosis: CIN 3 Surgeon: Dr.

Anesthesia: Local, 1% lidocaine with epinephrine, 5 mL

Procedure: LEEP

Indications: The patient is a 35-year-old female with a history of several abnormal Pap smears including the most recent with HSIL. She underwent colposcopy with biopsy revealing a large CIN 3 lesion. After discussion of the options for treatment, the patient prefers LEEP.

Procedure: Informed consent was obtained and prior colposcopic findings were reviewed. The patient was placed in the dorsal lithotomy position and an insulated vaginal speculum was introduced with good visualization of the cervix. Acetic acid was applied and the previously noted lesion at 3 o'clock was again visualized under colposcopic magnification as was the entire squamocolumnar junction. No other abnormalities were noted. Lugol's solution was applied and the cervix again visualized with the colposcope. Anesthesia was provided with injections of 1%

lidocaine with epinephrine at 3, 6, 9, and 12 o'clock just peripheral to the transformation zone. Approximately 5 mL was used in total. After adequate anesthesia was confirmed, a round 2.0 cm by 0.8 cm loop electrode was used on a pure cutting setting at 35 watts to remove the entire transformation zone in one pass. The edges of the lesion were visualized and included in the excision. There was minimal bleeding, which was controlled with coagulation using a ball electrode. Monsel's solution was applied prior to removing the speculum. Patient tolerated the procedure with minimal discomfort.

Estimated blood loss: Negligible

Specimen removed: One cervical specimen removed and sent to pathology

Complications: None

#### **COMMON ERRORS**

- The patient experiences an electric shock. Using a coated, nonconductive speculum prevents electric shock, which is caused by touching the speculum with the electrode during the procedure. An "electric shock" sensation can make the patient jump, causing significant injury.
- The loop electrode "stalls" as it is going through the tissue. Possible causes include the following:
  - If using a reusable loop, it must be free of carbon. Use a piece
    of fine sandpaper to shine the loops before the procedure.
    When using disposable loops, this will not be a problem.
  - The operator is moving the loop too quickly through the tissue. Go fast enough to prevent excessive tissue damage but slow enough to maintain a cutting function.
  - The cutting power is too low on the unit. Often, a pure cutting current will be easier to use than the "cut and coag" mode.

• The unit has an automatic shut-off and the patient is not grounded. Check that the grounding pad is securely inserted to the main unit and attached to the patient.

If a stall occurs for any reason, withdraw the electrode and either try passing it through the same tissue again after the problem has been corrected or approach from the other side.

- The electrode won't "cut" when touching the cervix. The electrode has not been activated before touching the patient or the tissue is too dry. In order for the electrode to cut, the tissue must be moist. Apply some acetic acid. Always activate the unit before touching the tissue with the loop.
- Pathologist reports excessive thermal damage on the tissue. Turn
  down the power on the unit or switch to the pure cutting mode
  for future procedures.

#### **COMPLICATIONS**

- Significant intraoperative bleeding is an uncommon but potentially serious complication. It sometimes occurs when the electrode is inserted too deeply into the tissue at the 3 and 9 o'clock positions (where the cervical branches of the uterine artery are located) or when the patient has severe cervicitis. The most effective way to control bleeding is to first apply pressure directly to the bleeding site using a large cotton-tipped applicator. Once the bleeding has slowed, the ball electrode is then placed in direct contact with the bleeding site and tissue is "desiccated" using coagulation current. If the bleeding is not controlled with pressure, the clinician should inject 1 to 2 mL of 2% lidocaine with epinephrine into the bleeding site. With the bleeding slowed or stopped, the ball electrode may then be effective. For rare cases of persistent bleeding a "figure of eight" hemostatic stitch can be placed or the vagina and cervix can be packed tightly with  $4 \times 4$  gauze and the patient transported to the emergency room.
- Postoperative bleeding occurs in less than 5% of patients. These
  patients experience a modest amount of bleeding 4 to 10 days
  after LEEP. It can usually be managed by electrofulguration or by
  packing the crater base with Monsel's paste. Minimal spotting is
  to be expected up to 14 days after the procedure and after initial
  intercourse.
- Post-treatment cervical stenosis (Fig. 149-10) is an uncommon complication (<1%) and occurs more commonly in postmenopausal women and those lacking estrogen stimulation (postmenopausal women; Implanon and Depo-Provera users; lactating women). For postmenopausal patients and hypoestrogenic states, consider replacement estrogen for 2 to 3 weeks after the procedure (one applicator of estrogen cream in the vagina every night).
- *Inadvertent burns or lacerations* to the lateral vaginal wall or other sites can occur but are rare. The clinician should instruct the

**Figure 149-10** Cervical stenosis following a loop electrosurgical excision procedure. (Courtesy of The Medical Procedures Center, PC, John L. Pfenninger, MD.)

- patient not to move. Ureters, bowel, and bladder are only millimeters away from the vaginal sidewalls.
- Pain and discomfort are minimal and generally can be controlled with nonsteroidal anti-inflammatory drugs (NSAIDs).
- Infection is rare. Metronidazole or doxycycline can be used.
- Recurrence or persistence of disease occurs in 5% to 10% of cases.
- Cervical incompetence. Although it is generally recognized that cold-knife conization is associated with adverse obstetric outcomes, most of the studies published in the early 1990s showed little impact of LEEP on obstetric outcomes. Recently larger studies have been published and these newer studies indicate that all forms of excisional procedures used to treat CIN produce similar obstetric risks. A meta-analysis of these published trials found that LEEP has a significant association with preterm delivery (11% risk in treated women versus 7% risk in untreated women), low-birth-weight infants (8% in treated women versus 4% in untreated women), and premature rupture of membranes (5% in treated women versus 2% in untreated women). Therefore, when treating women likely to become pregnant in the future, consideration should be given to using an ablative method such cryotherapy rather than LEEP, provided the colposcopy is satisfactory and there is no suspicion of occult invasive cancer.

#### POSTPROCEDURE MANAGEMENT

Patients are seen 4 to 6 weeks after the procedure for a review of the pathology report and for a brief postoperative check. This visit helps reassure the patients and decreases their anxiety about how well they have healed. It also provides an opportunity to reinforce prevention methods, such as not smoking. It is important to check for cervical stenosis. The os is easier to dilate early rather than waiting for a more mature scar (see Chapter 136, Cervical Stenosis and Cervical Dilation).

The clinician should then reevaluate the patient using either a program of repeat cytologic examination at 6 and 12 months, a single HPV DNA test for high-risk types of HPV at 6 to 12 months, or a combination of cytologic examination and colposcopy at 6 and 12 months. If a program of repeat cytologic examination is used for follow-up, patients with a cytologic result of atypical squamous cells or higher classification should be referred for colposcopy. If HPV DNA testing at 6 to 12 months is used, patients with high-risk types of HPV identified should be referred for colposcopy.

#### POSTPROCEDURE PATIENT EDUCATION

See the sample patient education handout online at www. expertconsult.com.

- The clinician should instruct the patient to avoid vaginal intercourse, douching, use of tampons, and heavy exercise (especially weight lifting) for 3 weeks.
- If significant bleeding persists for more than 2 weeks (if the volume is comparable to that of a normal period or greater), if the patient begins passing large blood clots, if the vaginal discharge becomes foul smelling, or if there is significant pelvic pain (especially if it is associated with a fever), the patient should call the physician or return to the clinic.

#### INTERPRETATION OF RESULTS

The specimen removed during LEEP should be sent to pathology as previously discussed. The pathologic diagnosis should confirm the prior biopsy and examination findings. The extent of dysplasia and involvement of the margins of resection will be reported. If invasive carcinoma is present, immediate reevaluation and follow-up are essential and the patient is generally referred to a gynecologic oncologist. Ideally, the lesion should be completely excised and the margins should be clear of any abnormal findings. If the ectocervical

or endocervical excisional margins are "positive" on histologic examination or if the ECC is positive for neoplasia, the patient is at higher risk for recurrence. However, even in these situations, less than one third of lesions will persist. The cautery and inflammatory response appears to resolve most of these. In these cases it is prudent to perform colposcopy with endocervical curettage and repeat cytologic examination approximately 3 to 4 months after the initial LEEP. In some instances, especially high-risk and postmenopausal patients, consideration should be given to performing a repeat diagnostic conization procedure (e.g., either a cold-knife or LEEP conization) once the cervix has healed.

#### **CPT/BILLING CODES**

- 57460 Colposcopy with loop electrode excision or excisions of the cervix (LEEP)
- 57461 Colposcopy with loop electrode conization of cervix (LEEP cone)
- 57500 Cervical biopsy
- 57505 Endocervical curettage
- 57520 Cervical conization, with or without fulguration (cold knife or laser)
- 57522 Cervical conization using loop electrode technique (LEEP cone)
- 99070 Supplies and materials for kits and electrodes (a surgical tray charge is generally allowed for an office LEEP)

# FERTILITY AWARENESS—BASED METHODS OF CONTRACEPTION (NATURAL FAMILY PLANNING)

William Ellert

Fertility awareness—based (FAB) methods of contraception are frequently referred to as *natural family planning* (NFP). FAB methods are an approach to contraception that identifies the days of the menstrual cycle when couples should avoid unprotected intercourse as determined by the normal physiology of the menstrual cycle and the life expectancy of a sperm and ovum. Studies in multiple countries have shown that couples choose this method of contraception for a variety reasons, the most common of which are health issues and concerns about side effects of other methods. Other reasons include financial concerns, religious beliefs, and a belief that "natural" is better.

Currently, six major methods are discussed when referring to FAB methods of contraception. Two are considered "historical methods," and four methods are currently considered more practical for clinical use.

The historical methods are

- Calendar rhythm
- Basal body temperature (BBT)

The current FAB methods are

- Standard Days method
- Ovulation method
- TwoDay method
- Symptothermal method

#### **PHYSIOLOGY**

The physiologic basis of the Standard Days method is based on hormonal studies indicating that a woman is generally fertile 5 days before ovulation and 24 hours after ovulation. This conclusion is based on the viability of the sperm after sexual intercourse being no more than 5 days and the viability of the egg after ovulation being less than 24 hours. Based on these studies, the probability of pregnancy from unprotected intercourse is as follows:

- 4% 5 days before ovulation
- 25% to 28% for the 2 days before ovulation
- 8% to 10% for the 24 hours after ovulation
- 0% for the remainder of the cycle

The remaining three methods for current FAB contraception rely on interpretation of the physiologic signs of fertility. Before ovulation, estradiol levels increase and cause the production of characteristic cervical secretions. The environment created by estradiol production is conducive to the transportation of sperm to the

ovum. After ovulation, progesterone produced by the corpus luteum causes a distinct change in the secretions. There is a typical obvious pattern to the secretions. No noticeable vaginal secretions are present for approximately 3 to 4 days after menstruation. After this, there is a distinctly sticky and elastic secretion that lasts for approximately 3 to 4 days. After this, the secretions turn clear and wet for approximately 3 to 4 days. Then, there is again an absence of secretions for approximately 11 to 14 days before the next menstrual cycle. This pattern is seen in the typical menstrual cycle lasting 26 to 32 days (Fig. 150-1).

#### **INDICATIONS**

Fertility awareness—based methods of preventing pregnancy are indicated for those couples who wish to avoid hormone-based and operative-based methods of contraception; who wish to minimize the use of barrier methods of contraception; and who are able to avoid unprotected intercourse on fertile days. These methods require the active participation of both partners and a willingness to assess the signs of fertility daily. The ability to use modern methods of FAB contraception relies ultimately on the acceptance of the technique(s) by physicians and other health care providers as legitimate and effective methods of family planning. The availability of trained instructors and other resources that readily convey the needed information is also crucial. These methods of fertility awareness are also very helpful for couples who desire pregnancy.

#### **CONTRAINDICATIONS**

There are no absolute contraindications to these methods of contraception. Relative contraindications are related to an unreliable hormone status and include the following:

- Breast-feeding
- Recent menarche
- Recent childbirth
- Recent discontinuation of some hormonal contraceptives
- Perimenopausal
- Menstrual cycles that are frequently shorter than 26 days or longer than 32 days (for the Standard Days method)
- Persistent reproductive tract infections that affect the signs of fertility
- · An inability to interpret the signs of fertility correctly

Most of these relative contraindications can be overcome through more extensive counseling and follow-up.

Figure 150-1 Physical signs associated with days of the typical 28-day menstrual cycle.

#### **METHODS**

#### **Historical Methods**

The calendar rhythm method and the basal body temperature method are rarely used by practitioners familiar with more current FAB methods of contraception. The *calendar rhythm method* consists of recording the length of six cycles. Eighteen days are subtracted for the number of days in the shortest cycle and 11 days are subtracted from the number of days in the longest cycle. This determines the period in which sexual intercourse should be avoided. For example, if the shortest cycle is 23 days and the longest cycle is 31 days, then the fertile period is from day 5 until day 20.

The basal body temperature method is based on the fact that in a normal cycle, the basal body temperature is approximately 0.5° F (0.3° C) higher in the luteal phase than in the follicular phase. This method requires avoiding unprotected sexual intercourse from the beginning of the cycle until 3 days of elevated temperatures have occurred. This method requires the daily monitoring of temperature before any activity or food consumption.

#### **Current Methods**

#### Standard Days Method

- Screening: The Standard Days method is appropriate for women whose cycles are usually between 26 to 32 days long. Women who have more than one cycle outside of the 26- to 32-day range in a 12-month period should be encouraged to use another method.
- Instructions: Avoid unprotected intercourse from day 8 of the cycle through day 19. Day 1 is defined as the first day of menstrual bleeding.

#### **Ovulation Method**

- Screening: This method is appropriate for women regardless of their cycle length. Women who are breast-feeding, have recently used hormonal contraception, or who are perimenopausal require more detailed counseling and instructions.
- Instructions: This method requires women to observe, record, and
  interpret their cervical secretions at the vulva several times each
  day, generally before each urination. Women are taught to chart
  the days of their menses, the days with secretions (including the
  characteristics of secretions), and the days when pregnancy is
  likely. Unprotected intercourse is to be avoided at the following
  times:
  - During menses (because menstrual bleeding could obscure the presence of secretions).
  - On preovulatory days after days with intercourse (because of the possible confusion with semen).
  - On all days with fertile secretions (see description under "Physiology").

#### TwoDay Method

 Screening: The screening criteria for this method are identical to those for the ovulation method. • Instructions: This method is very similar to the ovulation method, but is much simpler. The TwoDay method also requires women to determine the presence or absence of cervical secretions. Two questions are then asked: "Were there any secretions today?" and "Were there any secretions yesterday?" If the patient notes 2 consecutive days without secretions she is deemed to be in a nonfertile period. If the answer to either of those questions is "yes," she is potentially fertile on that day.

#### Symptothermal Method

- Screening: The screening criteria for this method are identical to those for the ovulation method.
- Instructions: The symptothermal method allows for several different "rules" for avoiding pregnancy. Each rule recognizes the appearance of cervical mucus at the vulva or vagina as the first sign of fertility. In determining the end of the fertile window, couples may choose to emphasize mucus observations over temperature observations (and vice versa). The most conservative rule recognizes both observations equally. For example, post-ovulatory infertility commences after the third day (or more) of a thermal shift (>0.4° F), cross-checked by 4 or more days of "drying up" of the cervical mucus. This allows the couple to personalize their method and focus on a marker they prefer, while still using an alternative to "back-up" their primary marker.

#### **EFFICACY**

The effectiveness of FAB methods of contraception, when taught and used correctly (i.e., method effectiveness), ranges from 97% to 100% in all published studies. It must be emphasized, however, that these methods rely on the ability of the couple to abstain from genital contact during periods of fertility, and the "use effectiveness" rate typically approaches about 80%.

#### **CONCLUSION**

Fertility awareness—based methods of avoiding pregnancy (or facilitating pregnancy) are very useful tools for women to become more aware of and knowledgeable about the physiologic changes that occur during their menstrual cycle. Frequently this can be used to facilitate communication between partners regarding mutual reproductive responsibility. The personal choice of a couple to choose this method of contraception should be supported by primary care providers in a responsible and informed manner.

## PAP SMEAR AND RELATED TECHNIQUES FOR CERVICAL CANCER SCREENING

Gary R. Newkirk

Despite the controversies surrounding cervical Papanicolaou (Pap) smear testing, it remains an effective tool for cancer prevention and detection. Numerous studies have documented a statistically valid drop in the incidence and mortality rates of invasive cervical carcinomas since the introduction of the Pap smear. Unfortunately, cervical cancer screening has not eradicated this potentially preventable disease. The current cervical cancer detection system relies on a complex system of clinical and laboratory procedures that have potential for error at numerous points. Koss' (1989) landmark discussion summarizes major sources of error, including (1) problems with the initial clinical examination, (2) inappropriate smear collection technique, (3) laboratory errors in sample preparation and interpretation, (4) errors in report interpretation, (5) failure of the clinician to understand or appropriately respond to Pap smeargenerated data, and (6) failure of the patient to follow the clinician's recommendations.

Compelling data link cervical intraepithelial neoplasia (CIN) with human papillomavirus (HPV) infection. Epidemiologic data further document the epidemic proportions of new genital HPV infections. Box 151-1 summarizes these risk factors for cervical dysplasia. Most women who are exposed to HPV have transient infections and do not develop cervical cancer. Current evidence indicates that patients with the persistence of HPV as detected by either abnormal cytologic features (Pap) with or without positive high-risk HPV DNA testing (see Chapter 142, Human Papillomavirus DNA Typing) are the subgroup of women who remain at greatest risk for developing cervical cancer. Despite the success of Pap smear screening methodology, numerous studies indicate that there remains between a 20% and 50% false-negative rate for a single Pap smear in identifying patients with cervical dysplasia, and this includes even the latest ThinPrep method. Accordingly, the clinician should be aware that Pap smear screening guidelines are evolving to take in consideration not only the enhanced sensitivity of screening, but also the enhanced specificity of combining cytologic findings with high-risk HPV DNA results.

Furthermore, the sampling devices, method of preparation, and transport systems for Pap samples are evolving as well. Liquid-based Pap systems such as ThinPrep and SurePath are currently approved by the U.S. Food and Drug Administration (FDA) as alternatives to conventional slide smear techniques for Pap sample preparation. Liquid-based Pap smear cytologic examination also allows simultaneous collection of material that can be submitted for HPV DNA testing at the request of the clinician or as a "reflex" test dependent on the cytologic interpretation (see Chapter 142, Human Papillomavirus DNA Typing and the ASCCP Guidelines in Appendix K). *Reflex testing* means the DNA testing is automatically performed if an ASC-US (atypical squamous cells of undetermined significance) Pap smear is found. As a result of these advancements and a better

understanding of HPV screening, cervical cancer screening guidelines have become more complicated.

Clinicians are advised to keep current regarding the seemingly ever-changing cervical cancer screening recommendations because these guidelines will continue to evolve as new evidence-based and outcome data become available. At the present time, clinicians can continue to make significant contributions to cancer prevention in women by refining their method of Pap smear sampling, enhancing their understanding of Pap smear report interpretation, clarifying their recommendations for patient management, and making sure that their efforts are implemented by an effective follow-up and intervention system. Clearly, efforts to prevent cervical cancer are inconsequential if mechanisms for follow-up and quality assurance are not developed. Unfortunately, nearly 70 years after the advent of Dr. Papanicolaou's revolution with cervical cancer prevention, nearly 50% of the women who develop cervical cancer in the United States have either never had a single Pap test or have not had a Pap smear for 10 years prior to their diagnosis! This is unacceptable in this modern age of medical care.

This chapter focuses on a contemporary approach to Pap smear screening; it is assumed that basic pelvic examination skills have been mastered. Box 151-2 offers a brief summary of the terminology used throughout this discussion.

#### Box 151-1. Risk Factors and Historical Characteristics Correlated with Abnormalities on Pap Smear

Diethylstilbestrol (DES) exposure (should be extremely rare now)

Early age at first intercourse (before age 16 years)

History of abnormal Pap smear, cervical dysplasia, or cervical cancer

History of genital or anal condyloma

History of sexual abuse

History of vulvar dysplasia

Illicit drug use (intravenous or oral)

Immunocompromised patient, including HIV-positive status

Multiple sexual partners (more than three)

Other sexually transmitted disease history

Sexual partner with condyloma or history of intercourse with a woman with cervical dysplasia or cancer

Sexual partner with more than three previous sexual partners Tobacco smoking

HIV, human immunodeficiency virus; Pap, Papanicolaou.

#### Box 151-2. Terminology and Definitions

- Atypical glandular cells (AGC): In the past these were called "AGC-US" (atypical glandular cells of undetermined significance), but because the incidence of significant pathology is so high with this finding (10% cancers and 25% high-grade lesions), the "US" has been dropped by Bethesda-2001. All AGC reports need further investigation.
- Atypical squamous cells (ASC): Bethesda-2001 divides these into ASC-US (atypical squamous cells of undetermined significance) and ASC-H (atypical squamous cells, cannot exclude HSIL).
- Carcinoma in situ (CIS): Dysplasia involves the entire squamous epithelium but does *not* penetrate the basement membrane. Included in CIN 3 and HGSIL designations.
- Cervical intraepithelial neoplasia (CIN): See "Dysplasia." CIN 1 refers to mild dysplasia, CIN 2 to moderate dysplasia, and CIN 3 to severe dysplasia, including carcinoma in situ (CIS).
- Columnar epithelium: Single-layer, mucin-secreting epithelium on the surface of the endocervix. It can often be seen on the ectocervix and is proximal to the SCJ.
- Dysplasia: Premalignant change in the cervical epithelium displaying proliferation of parabasal cells with disordered polarity, loss of cellular junctions, coarse nuclear chromatin clumping, abnormal nuclear cytoplasmic ratio, and high mitotic index. Reported as mild, moderate, and severe dysplasia. Usually refers to histologic features.
- *Ectocervix* (also called exocervix): The flat portion of the cervix that is readily visible. The cervical os is located centrally.
- Endocervical cells: Glandular, columnar-shaped cells obtained from the endocervical (columnar) epithelium in the endocervical canal.
- *Endocervix*: The area within the endocervical canal. *Exocervix*: See "Ectocervix."
- Frankly invasive squamous cell carcinoma of the cervix: Invasion greater than 3 mm (or 5 mm, depending on classification used) below the basement membrane.
- Koilocytotic or koilocytic: Equivalent terms include condylomatous atypia and human papillomavirus (HPV)

- effect; these terms describe cells that have perinuclear halos or vacuoles that vary in shape and configuration, and that show a distinct zone of clearing between the nucleus and cytoplasmic membrane. The abnormal nuclei are characterized by wrinkling, variation in size and shape, binucleate forms, and hyperchromasia. Usually indicative of HPV infection.
- Microinvasive cervical cancer: Invasion 3 mm or less below the basement membrane. Some terminologies allow 5 mm of invasion and include other descriptive factors.
- Reflex DNA testing: Automatically obtaining HPV DNA test for patients that have an ASC-US report.
- Squamocolumnar junction (SCJ): The line where the squamous epithelium of the ectocervix joins the mucus-secreting columnar epithelium of the endocervix.
- Squamous cells: Epithelial cells on the surface of the ectocervix. These cells appear smooth and pink on the cervix.
- Squamous intraepithelial lesion (SIL): Reported as either low-grade (LGSIL, LSIL) or high-grade (HGSIL, HSIL), corresponding to increasing severity of dysplasia (Bethesda terminology). Originally referred to cytologic diagnosis, but now often used to describe histologic findings as well.
- Squamous metaplasia: A type of tissue present where the columnar epithelium is being replaced (transformed) by squamous epithelium. This normal tissue occurs within the cervical transformation zone, and the transformation of columnar to squamous epithelium is a totally normal process.
- Transformation zone (TZ): Area of transformation or replacement of the cervical columnar epithelium by squamous epithelium through a process called metaplastic change. The active TZ goes from the outermost gland to the SCJ. The TZ is the principal site of origin for precancerous and invasive squamous cell carcinomas of the cervix.

See Figures 151-1 and 151-2, and Chapter 137, Colposcopic Evanination

#### **A**NATOMY

Figure 151-1 depicts the anatomy involved. Successful Pap smear technique requires sampling from the active transformation zone in women with an intact cervix or from the vaginal cuff for those who have undergone hysterectomy. Figure 151-2 provides a graphic representation of the changes involved with preinvasive and invasive disease of the cervix as well as a depiction of histologic and cytologic correlates. (Refer to Chapter 137, Colposcopic Examination, for further discussion of anatomy.)

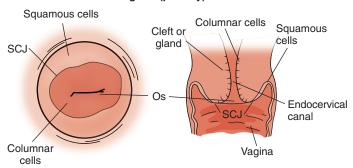

#### **INDICATIONS**

The Pap smear is a screening test only; it is not diagnostic. Thus, if an abnormality is seen or palpated at the time of the pelvic examination, it should be examined with a colposcope and a directed biopsy performed. The physician cannot rely on the Pap smear alone to be diagnostic for an observed lesion.

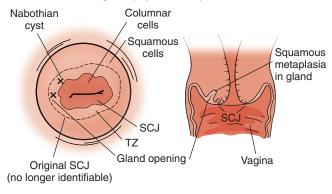

Screening: Current cervical cancer screening guidelines are summarized in Box 151-3. These guidelines also consider recommen-

- dations concerning the use of liquid-based cytologic and HPV testing. Clinicians are advised to consider these guidelines in relation to the patient population they serve and their practice and patient resources.
- Follow-up after treatment for cervical dysplasia, malignancy: See the ASCCP Guidelines in Appendix K. All women with a history of cervical dysplasia remain at significant risk for disease recurrence and should undergo Pap smear testing at least annually for life. There are numerous schemes for follow-up after treatment for cervical dysplasia and carcinoma. All involve increased frequency of Pap smear testing or HPV testing for a period of time. Repeat colposcopic examination is often performed with endocervical curettage or cervical biopsy in circumstances where the clinician is concerned about the recurrence of cervical dysplasia or cancer.
- Diethylstilbestrol (DES)-exposed offspring: DES-exposed offspring require colposcopic evaluation (and repeat colposcopy with biopsy as necessary). Modified Pap smear and colposcopy protocols have been developed. The appropriate Pap smear follow-up usually requires modified routines determined by coordinated exchange of expert opinion between the clinician, pathologist,

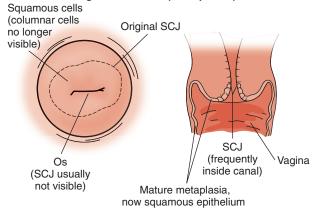

#### Age 12 (puberty)

#### Age 21 (reproductive)

#### Age 50 and older (menopausal)

**Figure 151-1** Appearance of cervix in various age groups. The area most at risk in all age groups is the transformation zone (TZ), including the squamocolumnar junction (SCJ). Note how location varies with age. The SCJ and TZ are readily visible in younger women and may be quite large. The SCJ migrates inward with aging, and by menopause, it is usually within the canal and is not visible. The entire TZ must be sampled to maximit efficacy of the Papanicolaou smear. Also see Figure 137-2 (Chapter 137, Colposcopic Examination) for cervical photographs showing these findings and developmental changes.

and, quite often, a gynecologist familiar with this small subgroup of women. The vagina must also be observed closely, because it has a much higher risk for dysplasia and cancer.

- Any visible or palpable lesion of the cervix: Follow the precaution that the Pap smear is not diagnostic and further assessment is usually done with a biopsy directed by the colposcope.
- Any abnormal vaginal bleeding or discharge.
- Following hysterectomy for benign disease: Discontinue Pap smears if for benign reasons and no prior history of high-grade CIN.

Exceptions include immunocompromised women or women who have a history of prenatal exposure to DES.

- Following hysterectomy for dysplasia, carcinoma: Continue Pap smears annually after three or four normal Pap smears at 4- to 6-month intervals.
- Supracervical (subtotal) hysterectomy: Routine recommendations should be followed.
- Victims of rape, incest, abuse: Pap smear is part of the initial work-up. Evaluations in these circumstances require expertise and strict adherence to medical/legal chain of evidence. (See Chapters 157, Treatment of the Adult Victim of Sexual Assault, and 158, Management of the Young Female as Possible Victim of Sexual Abuse.)

#### **CONTRAINDICATIONS**

#### **Absolute**

There are no absolute contraindications to obtaining a Pap smear.

#### Relative

Relative contraindications include clinical circumstances in which sample collection is difficult to obtain or difficult to interpret (e.g., active vaginitis or cervicitis, pelvic inflammatory disease [PID], or menses). The clinician must weigh the benefits versus the risk of obtaining the screening Pap smear under these circumstances. For instance, if a woman presents with abnormal vaginal bleeding, a Pap smear is advised, despite the presence of blood. This contrasts with a patient who comes in for a routine Pap smear screening and has begun to menstruate. In the latter instance, the Pap smear can be deferred to a more favorable time. See the sample patient education handout available online at www.expertconsult.com, which includes advice on what women can do to optimize Pap smear results.

#### **EQUIPMENT**

- Examination table appropriate for placing the patient in the lithotomy position
- A warm, well-lit examination room
- Various-sized speculums: Graves (metal); Pederson (metal); plastic, disposable (Welch Allyn, Inc; Durr-Fillauer Medical, Inc.)
- Water-soluble lubricant (e.g., K-Y Jelly)
- Nonsterile examination gloves
- Large swabs for gently blotting excess discharge
- Cotton swabs
- Method for warming the speculum (warm water or speculum drawer warmer [light bulb])
- Sampling devices (see Fig. 151-5)
- Wooden spatulas (Cervical Scraper No. 7, Hardwood Products Co.) or plastic spatula (Cervical Scraper [8½ inch], Milex Products) for ectocervical sample
- Cytobrush Plus for endocervical sample (Medscand)
- As an alternative to taking two samples, a "broom" device can be used for both the ectocervical and endocervical samples (Cervex-Brush, CooperSurgical, Inc.; Papette, Wallach Surgical Devices, Inc.)
- Microscope slides, fixative (consult with reference laboratory performing cytologic evaluation for its preference), or medium for liquid-based testing
- Appropriate patient identification, history forms to accompany Pap smear and other tests
- Culture or transport media and swabs as necessary for detection of gonorrhea, chlamydia, herpes, and fungal infection, and KOH/ wet mount
- Cervical tenaculum or cervical hook (rarely needed)
- · Ring forceps

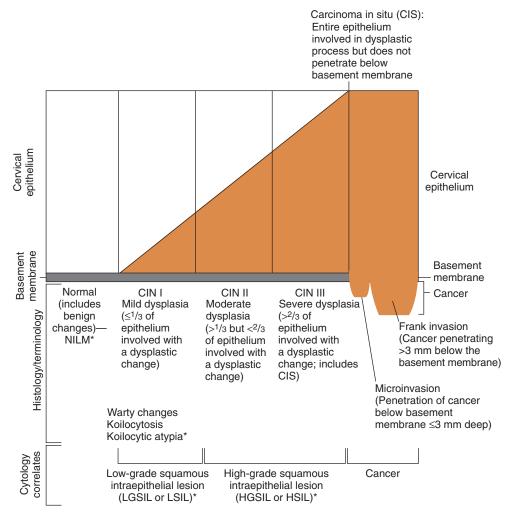

Figure 151-2 Histologic and cytologic correlations of various terms used to describe preinvasive and invasive squamous cell disease of the cervix. Also see Box 151-2 for further description of the terms. The degree of epithelial involvement correlates with the severity of cytologic findings as well as the total degree of involvement of the dysplastic tissue in relation to the thickness of the cervical squamous epithelium. On histologic examination, involvement below the basement membrane supports a diagnosis of invasive cancer. NILM, negative for intraepithelial lesion or malignancy. \*Atypical squamous cells (ASC), atypical squamous cells of undetermined significance (ASC-US), and atypical squamous cells that cannot exclude HSIL (ASC-H) are not depicted here because they include a variety of histologic diagnoses. Note, too, that glandular cell abnormalities include atypical glandular cells (AGC), endocervical adenocarcinoma in situ (AIS), and adenocarcinoma, and are also not depicted in this graph.

 Materials and solutions for liquid-based Pap smears (e.g., Thin-Prep)

#### **Sampling Devices**

Concern over the frequency and occurrence of false-negative Pap smears has led to the development of newer Pap smear sampling, preparation, and processing techniques. Despite the higher costs for the newer sampling devices (nominally \$0.40 to \$0.80 each), the increased quality of smears, the improved detection rates, and, ultimately, the fewer patients who must return for "inadequate" repeat smears more than justify this added expense. The routine use of the Cytobrush, Cervex-Brush, Papette, or similar devices is recommended (see later discussion of liquid-based technologies). A Pap smear consists of sampling the endocervical canal and the entire transformation zone (Figs. 151-3 and 151-4). At times, the broom device will not be wide enough to sample the entire area at risk (the transformation zone). Additional sampling of the missed area is then required. Clinicians should not be locked into using a single method of transformation zone sampling. A good strategy for obtaining ideal Pap smears is to have several types of sampling devices such as the brush and broom available. "One size fits all" strategies are less effective than using the sampling device that matches the patient's particular cervical anatomy.

The Pap smear test samples "exfoliated" cells. As such, the transformation zone need not be denuded of its mucosa to obtain an adequate sample! There are enough cells from one Cytobrush and a wooden spatula sample, for instance, to provide material for cyto-

logic interpretation for five slides! Sharp, fine-edged plastic devices are advocated by some physicians; however, wood works fine for sampling of the ectocervix. Both should be accompanied by brush sampling of the endocervical canal. A bloody Pap smear sample decreases detection rates. Figure 151-5 illustrates several of the common sampling devices that achieve satisfactory sampling.

#### **Liquid-Based Pap Smears**

In the United States there are two FDA-approved *liquid-based Pap smear systems* available. Both rely on a method of sampling the cervix that is similar or identical to conventional slide prepared smears, but they differ in the transport media and the technical methods of cytologic preparation. With liquid-based Pap smears, the same principles apply regarding collection of cells. The sample, however, instead of being spread on a glass slide, is "swished" in a vial of liquid that is subsequently processed to eliminate blood and other debris.

Prior study suggested that liquid-based Pap testing is more sensitive and specific than conventional slide methods; however, a recent systematic review and meta-analysis indicated that *liquid-based Pap smear testing is neither more sensitive nor more specific for high-grade CIN when compared with the conventional Pap test.* A clearer advantage of the liquid-based technique is that the residual cytologic material left over after the cytologic examination is completed in the laboratory can be used for HPV DNA testing. (Refer to Chapter 142, Human Papillomavirus DNA Typing, and Appendix K to guide when HPV testing may be useful.) In particular, the data

### Box 151-3. American Cancer Society Guidelines for the Early Detection of Cervical Neoplasia and Cancer, 2003–2009

#### 1. When to start screening

- Begin approximately 3 years after the onset of vaginal intercourse but no later than 21 years of age.
- Adolescents who may not need a Pap smear should still obtain appropriate preventive health care, including contraception and education, other screening, and treatment of sexually transmitted diseases.

#### 2. When to discontinue screening

- Women who are age 70 and older with an intact cervix and who have had three or more documented consecutive technically satisfactory, normal/negative cervical cytologic tests and no abnormal/positive cytologic tests within a 10-year period before age 70 may elect to cease cervical cancer screening.
- When comorbid or life-threatening illnesses are present, Pap smears are not needed.
- Screening should be continued for women older than 70 years:

If they have not been previously screened When previous Pap smear screening information is unavailable

If there was in utero exposure to diethylstilbestrol (DES) For immunocompromised women (including those with HIV-seropositive status)

For women older than 70 years who have tested positive for HPV DNA

#### 3. Screening after hysterectomy

- After a total hysterectomy with removal of the entire cervix for benign lesions, Pap smears using vaginal cytologic samples are not indicated.
- The presence of CIN 2/3 is not considered a "benign lesion," so continued screening would be indicated.
- Women who have had a subtotal hysterectomy (the cervix remains) should continue cervical cancer screening.
- With history of CIN 2/3, or if it is not possible to document the absence of the same prior to the hysterectomy, three documented consecutive technically satisfactory normal/negative cervical cytologic tests should be obtained before ceasing screening. In addition, there should have been no abnormal tests within the previous 10-year period.
- Women with DES exposure or history of cervical carcinoma should continue screening after hysterectomy as long as they are in reasonably good health and do not have a life-limiting chronic condition.

#### 4. Screening interval

 Perform annually with conventional cervical cytology smears or every 2 years using liquid-based cytologic test. At or after age 30 years, women who have had three consecutive technically satisfactory normal/negative cytologic results may be screened every 2 to 3 years (unless they have a history of in utero DES exposure, are HIV-seropositive, or are immunocompromised).

#### 5. New technologies

 The panel did not issue a statement on new technologies that are under development. These include aided visualization (i.e., speculoscopy), cervicography, computer-assisted screening devices,

- optical probe devices, self-collected vaginal samples for HPV DNA testing, and spectroscopy/electronic detection devices.
- Liquid-based Pap technology: As an alternative to conventional cervical cytologic smears, conventional screening may be performed every 2 years using liquidbased cytologic test; at or after age 30, women who have had three consecutive, technically satisfactory normal/negative cytologic results may be screened every 2 to 3 years (unless they have a history of in utero DES exposure, are HPV positive, or are immunocompromised).
- HPV/DNA testing with cytologic test: Primary cervical cancer screening has not been approved by the FDA. Should the FDA approve HPV DNA testing for primary screening, it would be reasonable to consider it for women age 30 and over, as an alternative to cervical cytologic testing alone. Cervical screening may be performed every 3 years using conventional or liquid-based cytologic test combined with a test for DNA for high-risk HPV types.

#### 6. Additional recommendations

- Patients need to be educated (especially teens) that a
  pelvic examination does not equate with a cytologic
  (Pap) test. They still need regular health care visits.
- No recommendation was made regarding pelvic and rectal examinations. They are not effective in detecting cervical cancer early enough, but there are other reasons to consider them. These should be discussed on an individual basis with the primary care physician.
- Referrals of women with low-grade lesions for colposcopy may be less necessary for adolescents given the self-limited nature of many low-grade squamous intraepithelial lesions (LSILs) in this age group. Detection and treatment of high-grade squamous intraepithelial lesions (HSILs) should be the goal of adolescent screening and referral.
- Health insurance payers should not exclude adolescents or women of any age from coverage for cervical health on the basis of false positive cytologic results and/or mild abnormalities on cervical cytologic test.
- Health insurance coverage for new cervical screening technology is not uniform. Patients should be advised of this by their primary care provider.
- There is considerable clinical evidence with the use of the cytobrush in pregnant women with no apparent complications.
- Cervical broom instruments and other single sampling instruments are comparable to the spatula and brush.
- An endocervical swab is less sensitive than an endocervical brush and its use is discouraged. It may be considered for pregnant women.

CIN, cervical intraepithelial neoplasia; DES, diethylstilbestrol; FDA, Food and Drug Administration; HIV, human immunodeficiency virus; HPV, human papillomavirus; Pap, Papanicolaou. Adapted from Smith RA, Cokkinides V, Brawley OW: Cancer screening in the United States, 2009: A review of current American Cancer Society guidelines and issues in cancer screening. CA Cancer J Clin 59:27–41, 2009.

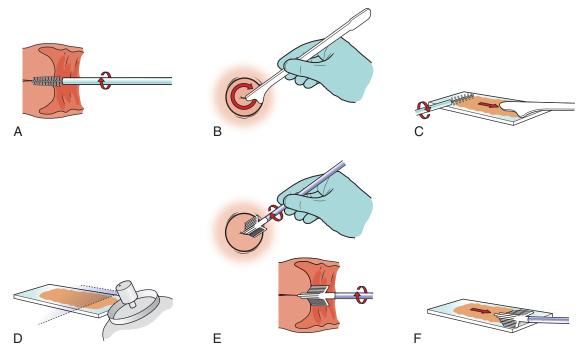

Figure 151-3 Obtaining the Papanicolaou smear. **A,** Endocervical sample with Cytobrush; rotate 90 to 180 degrees. **B,** Ectocervical sample obtained with a wooden or plastic spatula. **C,** A single-slide technique is preferred. First, the spatula sample is spread, which is then followed by "unrolling" of the brush sample directly over the first sample. **D,** Immediate fixation of the slide with cytologic fixative. **E,** Alternatively, a single sampling device may be used (Papette, Cervex-Brush, or "broom") to obtain both ectocervical and endocervical samples at the same time. Rotate 360 degrees five times. **F,** Spreading the sample from broom device onto slide.

support that reflex HPV testing will enhance management of women with ASC-US cytologic findings, separating those who need colposcopy (HPV DNA high-risk positive) from those who can be returned to standard screening (HPV DNA negative). If the HPV testing is performed automatically (reflex) based upon an ASC-US cytologic findings, the patient need not return for a separate HPV screening visit. Data support the cost effectiveness of this strategy. Furthermore, the combined use of liquid-based cytologic examination and same-time HPV testing has immediate advantage for management of women over age 30 and women in certain post-treatment categories (see Chapter 142, Human Papillomavirus DNA Sampling, and the ASCCP Guidelines in Appendix K).

In addition to the reflex HPV testing potential, liquid-based Pap techniques are also directly adaptable to computer-based automated screening devices. Development of automated screening devices has been driven more by the need to reduce labor costs than the need for accuracy. It is not clear that they will improve traditional human review of light microscopy samples. Currently these computer systems are utilized for either repeat evaluation of previously read Pap smears or for selecting certain cells for technicians to view. Computers can interpret only liquid-based preparations at the present time.

#### PREPROCEDURE PATIENT PREPARATION

The patient should understand the reason for performing the Pap smear. The Pap smear is best performed during midcycle. The patient should avoid douching, vaginal medications, and intercourse for 24 hours prior to the procedure. In most instances the examination should be rescheduled if the patient is actively menstruating. The patient should void before undressing for the examination. Make sure the room is warm enough and the speculum is warmed as well. Question the patient regarding her concerns. Not infrequently, women are hesitant to discuss symptoms related to the genitals, such as vaginal dryness, itchiness, or discharge, unless the

clinician asks. The clinician should explain each step of the pelvic examination prior to proceeding. Inform the patient of the mechanisms that you use to follow up on test results (Pap smear, cultures, etc.). (See the sample patient education handout online at www.expertconsult.com.)

#### **TECHNIQUE**

- Obtain history (especially sexual aspects of age at first intercourse, number of sexual partners, and history of sexual abuse or rape), perform review of systems, and answer questions. Clarify the patient's risk factors for cervical dysplasia. Review past Pap results if available.
- 2. Proceed with the general medical and breast examination, leaving the pelvic examination for last.
- 3. Label the frosted end of the glass slide or the liquid Pap vial with the patient's name and other identifying data prior to applying the sample.
- 4. Place the patient in the lithotomy position, and begin the examination. Wear nonsterile gloves. Inspect the vulva, and assess hair pattern, anatomy, estrogen effect, discharge, and any abnormal areas. Ask the patient if she has any concerns.
- 5. Place a small amount of water-soluble lubricant on the warmed speculum and insert it. Carefully advance the speculum, applying gentle pressure posteriorly. In patients whose vaginal walls prolapse and obstruct view, consider using a vaginal "stent." This can be fashioned by cutting off both ends of a single finger of a latex rubber glove and placing it over the blades of the speculum (Fig. 151-6). For those who are very obese or have excessively deep vaginas, a special, long "Snowman" speculum is available from CooperSurgical, Inc.
- 6. Adjust the speculum to obtain adequate visualization of the cervix, and tighten the screw or lock the speculum open.
- 7. Determine whether the vagina or cervix appears inflamed or infected. Avoid rubbing or otherwise traumatizing the cervix.

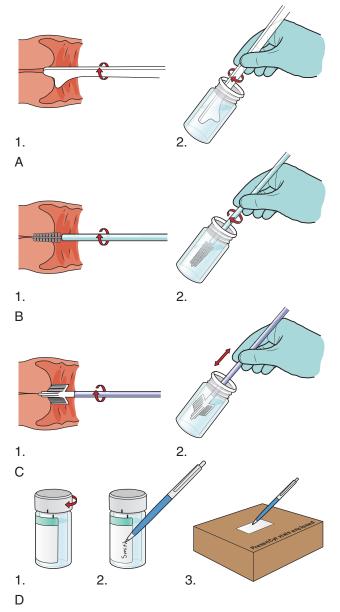

Figure 151-4 Liquid-based (ThinPrep) methods using plastic spatula (A), endocervical brush (B), or broom-like device (C). D shows the final three steps for each method. A, I. Obtain an adequate sampling from the ectocervix using a plastic spatula. 2. Rinse the spatula as quickly as possible into the PreservCyt Solution vial by swirling the spatula vigorously in the vial 10 times. Discard the spatula. B, 1. Obtain an adequate sampling from the endocervix using an endocervical brush device. Insert the brush into the cervix until only the bottom-most fibers are exposed. Slowly rotate 1/4 or 1/2 turn in one direction. Do not over-rotate. 2. Rinse the brush as guickly as possible into the PreservCyt Solution by rotating the device in the solution 10 times while pushing against the PreservCyt vial wall. Swirl the brush vigorously to further release material. Discard the brush. C, I. Obtain an adequate sampling from the cervix using a broom-like device. Insert the central bristles of the broom into the endocervical canal deep enough to allow the shorter bristles to fully contact the ectocervix. Push gently, and rotate the broom in a clockwise direction five times. 2. Rinse the broom as quickly as possible into the PreservCyt Solution vial by pushing the broom into the bottom of the vial 10 times, forcing the bristles apart. As a final step, swirl the broom vigorously to further release material. Discard the collection device. Be sure entire transformation zone has been sampled. D, I. Tighten the cap so that the torque line on the cap passes the torque line on the vial. 2. Record the patient's name and ID number on the vial, and record the patient information and medical history on the cytology requisition form. 3. Place the vial and requisition in a specimen bag for transport to the laboratory. (Courtesy of CYTYC Corp., Boxborough, MA.)

**Figure 151-5** Papanicolaou sampling devices. *Left to right:* Cervex-Brush, Cytobrush, wooden spatula, plastic spatula, tongue blade, and cotton swab. Use of the swab and tongue blade is discouraged.

- 8. *Identify cervical landmarks*, including the transformation zone with its squamocolumnar junction. Note the nature of the cervical mucus. Markedly excessive mucus or discharge may be gently blotted, not rubbed, from view. However, mucus may actually contain the exfoliated cells needed for the microscopic examination. So, unless truly necessary, do not remove this mucus; include it in the sample. Note any gross cervical lesions, such as erosions (ulcerations), leukoplakia (white areas), nabothian cysts, or condylomas. Examine the vaginal fornices for obvious abnormalities.
- 9. Obtain the Pap smear by using an endocervical sampling device (Cytobrush, Papette, or Cervex-Brush). Q-Tips are not to be used. If the Cytobrush is used, first insert the Cytobrush into the canal and rotate it 90 to 180 degrees. Do not rotate it more than this, since that may cause bleeding, which can wash away or obscure abnormal cells. Follow this by a gentle sampling of the entire transformation zone using a spatula device, rotating it 360 degrees. If broom devices (Papette, Cervex-Brush) are used, insert and rotate them 360 degrees five times. The broom will obtain both endocervical and ectocervical samples at the same time but must be rotated multiple times to collect an adequate number of cells.

Sampling the vaginal pool has little advantage during Pap smear screening unless the patient has had a hysterectomy. In this instance, be sure to sample the vaginal cuff itself. If vaginal abnormalities are seen, another Pap smear of these areas (using a spatula) may be submitted on a separate slide. Areas that appear abnormal on visualization will ultimately require colposcopy and biopsy.

#### 10. Glass slide method

• If a *one-slide smear technique* is suggested by your reference laboratory (check with your pathologist), withhold smearing the endocervical Cytobrush sample on the slide until the ectocervical spatula sample is smeared on the slide first. Once this is done, then quickly roll out the Cytobrush sample (which is less subject to drying artifact) right over the spatula smear material and spray immediately with cytofixative.

**Figure 151-6** Vaginal speculum stent. To aid in the visualization of the cervix, a single finger of a latex examination glove can be cut off and placed over the blades of a standard vaginal speculum. This is helpful if there is redundant vaginal mucosa, as seen with pregnancy, obesity, or multiparity.

- If a two-slide smear technique is used, each sample (ectocervical and endocervical) is evenly applied to different slides immediately after sampling, and then the slide is sprayed or dipped in preservative within 5 seconds. (The broom devices will provide only a single slide because they sample both the ectocervical and endocervical areas at the same time.)
- 11. If a thin-layer liquid-based technology Pap smear method is utilized, follow the instructions of the manufacturer, which usually require rinsing the Pap sample (collected on the brush, broom, or spatula) directly into a vial of transport liquid rather than smearing the sample on glass slides. (See later discussion under "ThinPrep Pap Smears.")
- 12. Perform the appropriate cervical cultures after cytologic sampling, if indicated. (The Centers for Disease Control [CDC] recommends that all sexually active females under age 25 be routinely screened for chlamydia and rechecked after treatment is completed.)
- Examine the vagina by slowly withdrawing the speculum, which
  is held slightly open, allowing the vagina to collapse over the
  blades. Note abnormalities.
- 14. Lubricate the gloved hand as necessary and *proceed with the bimanual examination*. Pay particular attention to palpated abnormalities of the introitus, vagina, fornices, and cervix. Palpate the areas of Skene's and Bartholin's glands. Ask your patient to bear down, and observe for uterine or pelvic floor prolapse and for leaking of urine. Having her cough facilitates assessment of pelvic support.
- Complete the remainder of the bimanual examination, noting the size, contour, tenderness, and mobility of the uterus and adnexal structures.
- 16. Perform a rectal examination on women with rectal complaints, or who are over age 40. Be sure to put on a new glove before the rectal examination, which may prevent the spread of HPV or other infectious agents to the anus. For women who have had abnormal high-grade Pap or biopsy results, a rectal examination may be indicated at any age because high-risk HPV viruses also cause anal cancers.
- 17. Allow the patient to dress.
- 18. Make sure the Pap smear requisition form includes all pertinent data regarding your patient. Include clinical findings, patient risk factors, or your concerns as part of this "referral" (Bethesda recommendation).

#### ThinPrep Pap Smears

- 1. Use a nonwooden spatula or supplied sampling device.
- 2. The Cytobrush should not be rotated more than 180 degrees, and only in one direction.
- 3. The collecting devices are then swished along the inner surface of the fluid container at least 20 times around.

#### SurePath Pap Smears

- 1. A cervical broom is provided with the transport fluid and vial.
- 2. Insert the central or longest bristles into the cervical canal.
- 3. Apply gentle pressure to allow the outer bristles to contact the cervix.
- 4. Rotate the broom five full turns in one direction making sure it samples the entire transformation zone.
- 5. Pop the broom head off into the transport vial.

#### Pap Smears during Pregnancy

During pregnancy, the cervix progressively enlarges, the squamocolumnar junction displaces outward, the mucus becomes thicker and more abundant, and the cervix becomes much more vascular. Extra care must be used to gently blot off excess mucus and when applying the Pap sampling device to collect the sample, especially after 20 weeks' gestation. Despite these changes, the Pap smear in a pregnant

woman maintains a similar sensitive and specific profile when compared to the nonpregnant state. Pregnancy itself does not accelerate or worsen cervical dysplasia. In most women, the first trimester cervix appears very similar to the nonpregnant cervix. The active transformation zone everts, or externalizes, progressively with advancing gestation, so there is little need to probe or sample the cervical canal, especially with wire tip brush devices. (In the author's opinion, broom or spatula devices are preferred in pregnancy, and the brush is avoided to reduce the risk of bleeding.)

- 1. Ideally, obtain the Pap smear as early in pregnancy as possible to avoid exaggerated spotting. Patients are also more uncomfortable in the lithotomy position with an advanced gestation.
- Although there is controversy with using brush devices in pregnancy, the broom or spatula devices make excellent sampling devices and are preferred.
- 3. Be gentle while rotating the brush because bleeding is more common in pregnancy.

#### SAMPLE PROCEDURE NOTE

This 32-year-old G3P3 white female is here for a screening Pap smear. She had a tubal ligation 4 years ago. Last Pap smear was 2 years ago. Prior Pap testing has been reviewed and is normal. With chaperone present and the patient in the lithotomy position, the external genitalia were inspected and found to be free of abnormality. A standard metal Graves speculum was warmed, lightly lubricated, and gently inserted. The cervix was manipulated into view and found to be free of inflammation, infection, and abnormal discharge. The squamocolumnar junction was seen in its entirety and was about 10 mm in diameter. A Cytobrush sample and spatula sample were obtained, sampling the entire visible transformation zone, and quickly smeared and fixed on a single identified glass slide. Cultures were not deemed necessary by history and examination. Bimanual examination revealed a smooth, midline, freely mobile, nontender uterus that was not enlarged. Ovaries and adnexal structures were of normal size and position and were not painful. No pelvic masses were identified. The vagina and cervix were normal on palpation.

#### **COMMON ERRORS**

- Lack of understanding of the basic anatomy of the cervix, including the squamocolumnar junction and the transformation zone can lead to incorrect sampling.
- 2. Inadequate exposure of the cervix with the speculum can lead to incomplete sampling of the transformation zone.
- Failure to review the patient's history for prior abnormal Pap smears or cervical treatment. The patient may require colposcopy (see the ASCCP Guidelines in Appendix K).
- Failure to inform or follow up with patients with Pap results, especially if abnormal.
- Not obtaining recent contact information from the patient, confounding attempts to notify the patient of Pap smear results.
- An aggressive approach to Pap smear sampling can lead to unnecessary bleeding, patient concern, and potentially less than satisfactory sample.
- Obtaining cervical cultures or DNA probes for sexually transmittable infections prior to the Pap smear may cause bleeding or remove valuable cytologic material from the Pap smear sample.
- 8. Relying on the Pap smear result even when the cervix appears abnormal. An abnormal-appearing cervix warrants colposcopy regardless of the Pap smear result.
- Interpretative confusion on the part of the clinician regarding the recommended follow-up of cytologic examination indicating atypical glandular cells versus atypical squamous cells (AGC vs. ASC-US, Bethesda-2001).

10. Inappropriately ordering DNA testing in women younger than 30 years of age for routine screening.

#### **COMPLICATIONS**

The Pap smear is only a screening test. False-negative rates are high (20% to 50%, with an average of 25%), and significant disease can be missed or underestimated. More frequent Pap smear screening or colposcopy may be indicated, depending on patient history and risks of having or developing genital malignancy. Minor spotting and occasional uterine cramps can commonly follow Pap smear sampling. Many of the shortfalls of Pap smear screening can be addressed by adhering to the following "golden rules":

- Identify cervical landmarks and gross abnormalities, and sample both the endocervical canal and the entire transformation zone. Choose a transformation zone sampler that fits your patient.
- All Pap smears reported as abnormal require some form of intervention. A report of dysplasia warrants colposcopy. Many clinicians also recommend colposcopy for reports of ASC, especially in patients with numerous risk factors. At the least, repeat Pap smear is indicated, or DNA typing is needed to determine which ASC Pap sample has high-risk HPV. Atypical glandular cells (AGCs) definitely need further evaluation. (See Chapter 137, Colposcopic Examination, and Appendix K, Management Guidelines for Abnormal Cervical Cancer Screening Tests and Histologic Findings.)
- Clarify your patient's risk factors for having HPV infection and cervical dysplasia as part of the routine examination. Anyone with substantial risks requires at least annual Pap smears.
- An observed abnormality on the cervix that cannot be readily explained by normal variants (e.g., nabothian cysts) warrants colposcopic examination. A normal Pap smear report in the face of an observed abnormal cervix should not dissuade the clinician from performing colposcopy and biopsy.
- Know your cytopathologist. Interpretive problems should be discussed directly with the pathologist, who can address your questions, including the option to review the cytologic findings at issue.
- The optimal way to reduce morbidity and mortality rates from cervical cancer may not be new technology, but rather convincing women who have not been screened for large intervals, or at all, to have a Pap smear.

#### POSTPROCEDURE MANAGEMENT

Most of the postprocedure management issues with the pelvic examination including Pap smear sampling can be addressed by environmental issues and having an informed patient. Inform the patient to expect minor spotting or cramping. This is especially important for Pap smears during pregnancy, when these symptoms can be very concerning. Make sure that you have accurate follow-up contact information and patient preferences for contact methods. Take time to explain when you feel the next Pap smear is due. With the new Pap smear screening recommendations, which may include HPV testing, patients and clinicians alike are often confused regarding what is recommended. Clearly document your recommendation.

#### INTERPRETATION OF RESULTS

#### **Adequacy**

The Pap smear report should indicate whether the smear was adequate. Unless the patient has had a hysterectomy, the report should include cytologic evidence that the transformation zone was sampled. Ordinarily, the reporting of endocervical cells along with squamous cells implies adequate sampling. Many cytologists attribute the same significance to "squamous metaplasia" as the reporting

of "endocervical cells present." Either is considered objective evidence that the transformation zone was sampled, which implies an adequate sample. Many reports will in some way use or check the word "adequate" on a form. Bethesda-2001 further delineates adequacy.

#### **Interpretation System**

The "Bethesda system," named after the national consensus conference for Pap smear interpretation, has provided a uniform nomenclature for Pap smear cytologic interpretation and attempts to address much of the confusion regarding Pap smear terminology. In September 2001, the Bethesda consensus conference convened for the third time and provided revisions of the reporting system, with general recommendations as follows:

- The Pap smear report should use terminology that is understood by the clinician.
- The clinician should be able to discuss the Pap smear report with the cytopathologist if questions arise.
- All abnormal Pap smears require some form of intervention in addition to the routine yearly screening interval.
- See the discussion in the following section regarding findings in postmenopausal women.

#### Follow-up Recommendations

A consensus group hosted by the American Society of Colposcopy and Cervical Pathology (ASCCP) convened in 2006 in Bethesda, Maryland, and developed guidelines for the management of abnormal cervical cytologic findings. These recommendations use the terminology of the 2001 Bethesda interpretation system and are applicable to clinical circumstances. (See also Chapter 137, Colposcopic Examination.) The ASCCP guidelines are summarized with algorithms that can be found in Appendix K. These algorithms can guide clinicians through evidence-based recommendations for the majority of abnormal Pap smear scenarios. General "new" tenets of these guidelines include the following:

- Less aggressive management of adolescents with abnormal Pap smears
- 2. A recommendation to avoid HPV screening in adolescents and those under 30 years of age.
- Options to use HPV testing for follow-up of ASC-US cytologic findings with reflex testing preferred if liquid-based Pap techniques are already used for cytologic evaluation.
- Specific suggestion for management of pregnant women with abnormal cytologic features.
- 5. Preferred recommendations for follow-up of both adolescent and nonadolescent women with low-grade squamous intraepithelial lesion (LSIL).
- Suggested work-up of women with initial and subsequent atypical glandular cells.
- 7. Use of HPV testing for screening and management of results in women age 30 years and older.
- Reconfirmation that all women with high-grade squamous intraepithelial lesion (HSIL) will require colposcopy. However, follow-up for high-grade dysplasias may differ for adolescent and nonadolescent women.
- 9. A statement that although these guidelines are based upon available evidence, they remain only guidelines and clinicians are advised to utilize them as they may apply to a specific patient and are encouraged to consider alternative management or follow-up strategies based upon the social, economic, risk stratification, and other factors that may influence management decisions.

A report describing glandular or adenomatous atypia (also called atypical glandular cells [AGC], and previously termed atypical glandular cells of uncertain significance [AGCUS], which is to be

differentiated from squamous atypia) warrants immediate colposcopy with endocervical curettage to rule out a high-grade lesion and cervical adenocarcinoma. Furthermore, *endometrial carcinoma* may be suggested by abnormal cytologic findings detected by a Pap smear. In such instances, formal endometrial sampling is mandated in patients over 40 years of age if no cervical abnormality is found. In *postmenopausal women* who are *not* on estrogen replacement, a report of *estrogen effect or endometrial cells* on the Pap smear is *not* normal. Evaluate the ovaries and uterus. If the findings of adenomatous atypia, or of estrogen effect/endometrial cells (in a postmenopausal woman not on estrogen) are definite, conization, pelvic ultrasound, and even laparoscopy may be indicated.

Patients who are *immunocompromised* (chronic immunosuppression after transplant, HIV positive, etc.) may require different, and in general more aggressive, follow-up and management strategies. Colposcopy is recommended for circumstance when there remains concern regarding potential severe or malignant changes.

From the 2006 ASCCP Guidelines, colposcopy is used for follow-up of the following Pap smear and pelvic examination findings:

- 1. Women with ASC-US
- 2. Adolescent women with HSIL or persistent ASC or LSIL
- 3. Women with LSIL
- 4. Nonadolescent women with LSIL or greater
- 5. Women with HSIL, both adolescent and nonadolescent
- 6. Initial work-up of women with AGCs
- Women over age 30 with either persistent abnormal cytologic features or positive HPV testing
- 8. Pelvic examination findings of
  - Abnormal-appearing cervix
  - Abnormal-feeling cervix or vagina

Other indications for colposcopy:

- DES offspring
- History of sexual abuse or rape
- Other sexually transmissible disease (relative)

#### **CPT/BILLING CODES**

Q0091	Screening Papanicolaou smear; obtaining, prepar-
	ing, and conveyance of cervical or vaginal smear to laboratory*
57500	Biopsy of cervix <sup>†</sup>
57505	Endocervical curettage <sup>†</sup>
88150	Pap smear interpretation <sup>‡</sup>
99201–99215	For a Pap smear, use office visit codes

#### **ICD-9-CM DIAGNOSTIC CODES**

622.0 622.2 622.7 622.8	Neoplasm of the cervix, benign Cervical carcinoma in situ, severe dysplasia of cervix Cervical ulcer Cervical leukoplakia Cervical polyp Cervical atrophy
	Cervical dysplasia, unspecified
233.1 622.0 622.2 622.7 622.8	Cervical carcinoma in situ, severe dysplasia of cerv Cervical ulcer Cervical leukoplakia Cervical polyp Cervical atrophy

<sup>\*</sup>One Pap test is covered by Medicare every 2 years for low-risk patients and every 1 year for high-risk patients. Q0091 can be reported with a separate E&M code for Medicare patients.

622.11	Mild dysplasia of cervix
622.12	Moderate dysplasia of cervix
623.8	Abnormal vaginal bleeding
626.8	Uterine bleeding
795.0	Abnormal Pap smear (some insurances will not reimburse
	for this code)
V15.89	Other specified personal history presenting hazards to
	health; other (for high-risk patients)
V76.2	Special screening for malignant neoplasms; cervix
V76.47	Special screening for malignant neoplasms; vagina

Very few clinicians (i.e., nonpathologists) interpret their patients' cytologic findings.

# PERMANENT FEMALE STERILIZATION (TUBAL LIGATION)

Gary R. Newkirk

In the United States, voluntary sterilization remains one of the most widely used contraceptive methods, chosen by nearly 20% of married women. Family physicians skilled with basic surgical technique are in an ideal position to discuss and perform permanent sterilization procedures for both men and women. Approximately 600,000 tubal ligations are performed each year in the United States. A similar number of vasectomies are carried out. No man has ever died from the vasectomy procedure itself. Between 10 and 14 women die each year (in the United States) from tubal ligation. The failure rate for vasectomy is 1 in 1200 in the United States, whereas tubal ligation failures occur in 1 in 200 procedures within the first year and may increase in frequency over time. Although vasectomy allows detection of failures, no simple technique allows the surgeon to find tubal ligation failures. The cost of a tubal ligation is five to six times that of an office vasectomy. When a patient asks about permanent contraception, it behooves the primary care physician to point out the benefits of vasectomy over a tubal ligation. Even the American College of Obstetricians and Gynecologists (ACOG) agrees that, all things considered, a vasectomy is the procedure of choice. Nevertheless, when vasectomy is inappropriate for any reason, tubal ligation remains an excellent choice for permanent surgical contraception.

Despite numerous variations, female sterilization consists of two basic steps: (1) exposing the fallopian tubes, and (2) partially resecting or occluding the tubes to prevent conception. This chapter discusses the minilaparotomy approach to permanent female sterilization, both as an interval and as a postpartum procedure.

Box 152-1 outlines basic terminology related to permanent female sterilization methodology. Minilaparotomy and laparoscopy are abdominal surgical approaches that are considered safe, quick, and readily available.

Table 152-1 shows advantages and disadvantages of the minilaparotomy and the laparoscopic techniques. Despite the recognized advantages of laparoscopy for certain situations, minilaparotomy—because of its reliance on readily available surgical equipment, fewer technical demands, and applicability to both interval and postpartum periods—is the method of choice for many primary care physicians. Box 152-2 summarizes the more common methods for ligating the tubes.

This chapter outlines the minilaparotomy approach and the modified Pomeroy or "Parkland" method for ligation (Figs. 152-1 and 152-2). The ideal method is still under debate; however, the modified Pomeroy and Parkland methods (with their variations) remain popular in the United States. Prudent physicians should identify patients who may benefit by referral, either for alternative methods that the referring physician cannot offer because of a lack of skill, training, equipment, or facility or because of the patient's clinical condition.

#### **ANATOMY**

Figure 152-3 demonstrates the anatomy relevant to a tubal ligation.

#### **INDICATIONS**

- Desire for permanent sterilization
- Medical conditions that place the patient at significant risk for irreversible morbidity or death if she should become pregnant
- Known severe inheritable genetic disease (that makes childbearing undesirable)

#### **CONTRAINDICATIONS**

#### **Absolute**

- Active peritoneal infections
- Severe chronic heart, lung, or metabolic disease (abdominal insufflation [laparoscopy] and the head-down [Trendelenburg] position can cause acute cardiopulmonary decompensation)
- Any unstable medical condition (including unstable postpartum condition)
- · Lack of informed consent
- Inability to tolerate necessary anesthesia
- Patient unsure of desire for permanent sterilization

#### Relative

- Prior significant pelvic or abdominal infection: minilaparotomy or laparoscopy may be more difficult. (Laparotomy may be necessary.)
- Severe obesity, especially with a history of pelvic or abdominal infection.
- Chronic heart disease, irregular pulse, uncontrolled hypertension, pelvic masses, uncontrolled diabetes, bleeding disorders, severe nutritional deficiencies, severe anemia, and umbilical or hiatal hernia. (The risks of future pregnancies must be weighed against the risks of permanent sterilization procedures.)

#### **EQUIPMENT**

- A laparotomy pack contains most of the instruments necessary for basic abdominal surgery and is available in most hospital outpatient and inpatient surgical suites.
- Suction catheter: Generally, suction is not used during a routine minilaparotomy tubal ligation. Suction is available on demand at most surgical suites; it is mandatory if complications such as bleeding develop.

#### Box 152-1. Female Sterilization Terminology

Colpotomy: A vaginal approach to tubal ligation through the posterior vaginal fornix.

Interval tubal ligation: Tubal ligation performed at times other than during the immediate postpartum periodgenerally 6 weeks or more after delivery.

Laparoscopy: Involves inserting an illuminated telescopelike instrument into the abdomen that allows visualization of the fallopian tubes in order to accomplish electrocoagulation or application of clips or rings. For open laparoscopy, a small incision is made within or just below the umbilicus to allow passage of a special cannula, around which the skin makes an airtight seal. The cannula allows for insufflation of the abdomen, passage of the laparoscope and instruments, and occlusion of the tubes. Open laparoscopy is considered safer than traditional closed laparoscopy, especially in women with prior pelvic or abdominal surgery or infection. With the closed laparoscopic procedure, the laparoscope is inserted blindly through the abdominal wall.

Laparotomy: A relatively large abdominal incision performed to optimize surgical exposure for a variety of intra-abdominal surgeries.

Minilaparotomy: Sometimes referred to as a minilap; involves a small abdominal incision, usually less than 5 cm (2 inches).

Postpartum tubal ligation: Tubal ligation performed within 72 hours of delivery.

Technical failure: Inability to complete the planned sterilization during the operation, which results in a change of method or failure to perform the sterilization.

	dvantages and Disa my and Laparoscop	
	Advantages	Disadvantages
Minilaparotomy	Easy to learn Basic surgical training and skill Inexpensive instruments Complications are usually minor Can be performed as a postpartum or interval	Takes longer than laparoscopy Difficult to perform on patients who are obese or who have pelvic scarring or adhesions Scar slightly larger More pain from the abdominal incision Higher infection rate than laparoscopy procedure
Laparoscopy	Very low complication rate Quick procedure (10–15 min) Very small incision Useful for other diagnostic and therapeutic purposes Less painful	Complications may be serious Requires abdominal insufflation, with its added risk More difficult to learn; requires specialized training for physician and staff Equipment is more expensive and requires more maintenance and repair Not recommended as a postpartum procedure

#### Box 152-2. Common Tubal Ligation Methods

#### Minilaparotomy ("Open" Procedure)

Electrocoagulation: A bipolar probe is passed through a small segment of tube to cauterize and obstruct the lumen.

**Fimbriectomy:** This method is accomplished by the complete removal of the fimbriated end of the tube. The procedure appears to have a higher pregnancy failure rate, and reversal is unlikely.

**Irving technique:** An extremely effective, though more difficult, method that cannot be reversed easily. The tube is cut and the uterine end buried beneath the peritoneum within the wall of the uterus. The remaining end is buried within the mesosalpinx.

Laparoscopy clips: Under laparoscopic guidance, clips are applied to occlude the tubal lumen. Hulka (springloaded) and Filshie clips (titanium and silicone rubber) are commonly used. Clips destroy less than 1 cm of tissue, and reversals are considered much easier.

Parkland technique: A small length of tube is separated from the mesosalpinx and ligated at each end, about 2 cm apart; the free segment between the ligatures is removed (see Fig. 152-3).

Pomeroy technique: The most common procedure performed for both interval and postpartum tubal ligations. Absorbable catgut sutures are used to tie the base of a loop of midportion (ampullary) tube. The ligated loop of tube is then removed. As the suture absorbs, the ends pull apart and are obstructed by the healing and scarring process. From 3 to 6 cm of the tube is destroyed (see Fig. 152-2).

Tubal ring: A small Silastic ring is stretched and placed over a loop of fallopian tube and then released. The tube is blocked by compression. Usually a 2- to 3-cm segment of the tube is involved. Reversal is more successful than with the electrocauterization, Irving, or Uchida techniques.

**Uchida technique:** A technically demanding, yet extremely effective, method that is becoming more popular in the United States. The tube is severed and the uterine end is buried within the mesosalpinx.

#### Vaginal Approaches

Ligation, clips, and electrocoagulation rings: Two varieties have been used.

- 1. Colpotomy, which involves a surgical incision in the posterior vaginal fornix through which the tube is delivered and occluded by ligation, clips, or rings.
- 2. Culdoscopy, in which a culdoscope is passed through a smaller colpotomy incision to allow identification of the tubes and application of the electroprobe, clips, or

Both of these less popular methods share higher complication and failure rates. They are not postpartum methods.

#### Transcervical Approaches

Essure: In the fall of 2002, the Food and Drug Administration approved a new method, called Essure, whereby a device with a small stainless steel inner coil and superelastic outer coil (4 cm  $\times$  0.8 mm, after release  $4 \text{ cm} \times 1.5-2 \text{ mm}$ ) is inserted hysteroscopically into the fallopian tubes for permanent sterilization. (See Chapter 148, Insertion of Essure [Hysteroscopically Assisted Female Sterilization].)

Others: Still considered experimental procedures, these methods of blocking the tubes from a transcervicalintrauterine approach continue to evoke interest. One method is to use Silastic "plugs" placed under hysteroscopic guidance. Various techniques are under development to provide a reversible sterilization by "pulling the plugs" when a pregnancy is desired.

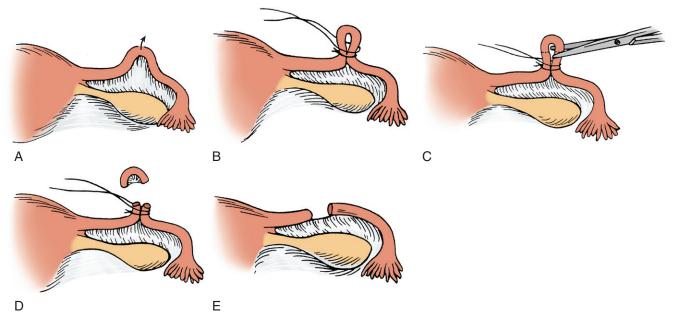

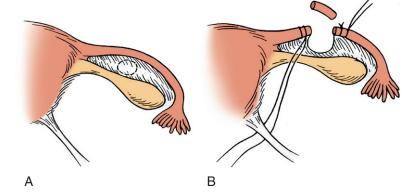

Figure 152-1 Modified Pomeroy technique. A, Lift loop. B, Double ligation 0 or 2-0 plain gut suture, no crushing. C, Each limb of tubal loop is cut separately. D, Loop is cut off. E, Later results.

**Figure 152-2** Parkland method of tubal ligation. **A,** A relatively avascular area of the mesosalpinx is identified within the isthmic portion of the tube. **B,** A segment of tube is isolated and removed after double ligation with chromic suture.

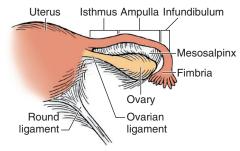

Figure 152-3 Basic anatomy of the parauterine structures.

- Coagulation device: Most operative suites have a Bovie or similar coagulation device available. Some surgeons prefer to have this available for all cases; others use this electively, or when complications develop. Because a Bovie requires grounding, it should be set up in advance. A ground plate can be attached before the patient is draped and scrubbed.

- 8-inch Babcock forceps to separate and retract fallopian tube (Fig. 152-4A)
- Ring sponge (a ring forceps holding a tightly folded gauze pad)
- Small Richardson or Army-Navy retractors for holding the incision open (Fig. 152-4B)
- Adson tissue forceps with teeth for skin manipulation (Fig. 152-4C)
- Metzenbaum scissors for general tissue blunt dissection and incision (Fig. 152-4D)
- Kelly clamps for blunt dissection, and for grasping and tagging suture, bleeders, or tissue planes (fascia, peritoneum)
- Uterine manipulators for use with the cervical tenaculum or the newer uterine manipulators (Fig. 152-4E)
- 5-mL, 0.5% bupivacaine (Marcaine) (optional)

#### **PRECAUTIONS**

Tubal ligation is elective surgery and should be performed when optimal preparation of both the patient and surgical environment are at hand. Patients must be competent to offer informed consent or the appropriate arrangements (legal guardianship for health care decisions) made to assure legal basis to proceed with permanent sterilization. As with all elective surgeries, the patient's medical condition should be optimized for the stress of regional or general anesthesia to allow for this intra-abdominal surgery. It is not uncommon to postpone a postpartum tubal ligation, which was planned

**Figure 152-4** Instruments for tubal ligation. **A,** Babcock forceps; **B,** small Richardson retractor; **C,** Adson tissue forceps; **D,** Metzenbaum scissors; **E,** uterine manipulator. (Also see Chapter 144, Hysterosalpingography and Sonohysterography.)

well in advance, because of intrapartum complications such as unexpected blood loss or unstable condition of the newborn. In these instances, delaying a postpartum tubal ligation as well as reevaluation for other contraceptive options may be prudent and appropriate.

#### PREPROCEDURE PATIENT PREPARATION

#### **Preprocedure Visits**

Preprocedure evaluation and counseling for women who want permanent sterilization warrant focused attention. A special visit should be scheduled to discuss contraceptive options, risks, technique, and follow-up demands of sterilization surgery. (See the sample patient education form online at www.expertconsult.com.) In addition, many insurance companies require preauthorization, which should be obtained at this visit. The counseling session should not be hurried or added to the end of a visit for an acute illness. Written materials should be given to the patient at this time. Federal payment programs require that counseling precede surgery by at least 30 days and not more than 180 days. Special forms need to be signed, and the patient must be at least 21 years of age. If the patient is involved in a monogamous relationship, it is wise to have the partner present during the consultation to address any concerns. Partner written consent is not mandatory, but if there is disagreement with this decision, it should be discussed and the reasons explored. It is also important to address the issues and benefits of vasectomy (refer to the opening paragraph of this chapter).

A preprocedure examination, which requires a reasonable amount of time, should occur within 10 days (some hospitals require less than 5 days) of anticipated surgery. Review the patient's complete medical history, paying particular attention to prior pelvic or abdominal surgery and infection. Are there drug allergies or drug intolerances? Are there medications (such as aspirin) that should be stopped? Is the patient on chronic anticoagulants? Is there a history of heart disease, diabetes, bleeding disorder, endometriosis, or dysfunctional uterine bleeding? Is other concomitant surgery necessary (e.g., dilation and curettage [D & C], breast biopsy, or procedure for urinary incontinence)? Is the Pap smear normal? Discuss the method of anesthesia that is to be used. Carefully review anticipated postprocedure morbidities (e.g., pain, the necessity of limited lifting). Remain mindful of the risk factors for regret (see later discussion under General Information). Review current contraceptive methods. Is pregnancy a possibility at the time of surgery? If the patient smokes, can she quit before surgery?

Preprocedure examination should be thorough. Focus on the heart, lung, breast, and abdominal examinations. During the pelvic

examination, assess for the presence of vulvar, vaginal, or cervical disease. Obtain specimens for culture (e.g., gonorrhea, chlamydia) as necessary. Assess the degree of uterine prolapse and urinary incontinence; have the patient bear down and cough. Perform a bimanual examination to assess uterine size, shape, and tenderness. Palpate the ovaries for enlargement. Pay particular attention to uterine mobility. Can the uterus be brought out of the pelvis easily, or is it frozen in a particular direction? Estimate the degree of abdominal wall obesity. Show the patient the location and size of the anticipated abdominal incision and eventual scarring.

Perform laboratory tests as necessary. Typically, hospitals require hemoglobin levels and a urinalysis as the minimum prerequisites for general anesthesia. Perform a pregnancy test if there is any question of pregnancy. If there is clinical evidence of cervicitis or pelvic inflammation, obtain specimens for culture, and treat the condition accordingly. In this case, schedule the surgery only when treatment and clinical response have been adequate.

Many same-day and outpatient surgery services offer *preanesthesia* counseling. The patient can meet with the anesthesia clinician to discuss anesthesia, risks, time to arrive at the hospital, how long to fast before surgery, and other issues. This counseling should be used whenever it is available; for many hospitals, it is a requirement.

Call the hospital surgery personnel with any special requests for the anticipated surgery. Will a D & C be performed? (If so, it should be done *after* minilaparotomy.) Is a uterine manipulator necessary, and what type will be used?

#### **General Information**

- Minilaparotomy is the safest sterilization method in the postpartum period, with a complication rate approaching that of interval sterilization, which is usually less than 3%. Laparoscopy is not as safe during the immediate postpartum period as at other times.
- Average rates for tubal sterilization failures are 1 in 250 at 1 year.
- Postpartum and postabortion sterilization appears to be somewhat less effective than interval sterilization.
- Of the women who have tubal sterilization, 1% to 2% seek reversal; however, sterility is not easily reversed. Only 30% to 70% of these women are candidates for reversal surgery (this broad range for reversal success is related to the original method of the tubal ligations), and pregnancy occurs in about 50% of those who do undergo reversal procedures. Reversal is most successful if less than 3 cm of the tubes was originally damaged or removed. The most "reversible" techniques include those that do not involve electrocautery and those in which the smallest segment is removed from within the isthmic portion of the tube. Women with the following risk factors for regret should not necessarily be denied surgery; however, the prudent physician should counsel these patients before performing sterilization.
  - Marital disharmony at the time of sterilization. (Remarriage is the reason 90% of women request reversal.)
  - Age less than 30 years at the time of sterilization. (Some clinicians debate whether this is a significant risk factor.)
  - Religious, socioeconomic, and educational backgrounds show much less correlation with regret. Low parity or number of live children is also less well correlated.
  - Regret may be slightly more prevalent after postpartum sterilization procedures; however, as a risk factor, this is less well defined.
  - Regret is more likely when sterilization is chosen because of financial difficulties, health, or emotional problems.

#### **PROCEDURE**

Figure 152-5 illustrates the procedure for tubal ligation. According to the latest ACOG and American Heart Association guidelines, prophylactic antibiotics are not indicated for laparoscopy or laparotomy sterilization procedures.

Figure 152-5 Procedure for tubal ligation. **A,** A transverse abdominal incision is made about 6 cm above the top of the symphysis pubis and about 5 cm wide. **B,** A small retractor is used to part the incised tissue and improve exposure as the incision is carried through the abdominal wall. **C,** Small bleeders encountered can be grasped with a hemostat and coagulated by touching the electrosurgical coagulator to the hemostat. **D,** As the fascia is encountered, it is carefully divided transversely and the incision is carried down to the peritoneum. **E,** The peritoneum is identified by its thin, translucent quality and is divided entering the abdominal cavity. **F,** A small Richardson retractor with counter-retraction by the surgeon's fingers improves visual access to the abdominal contents.

Figure continues on following page

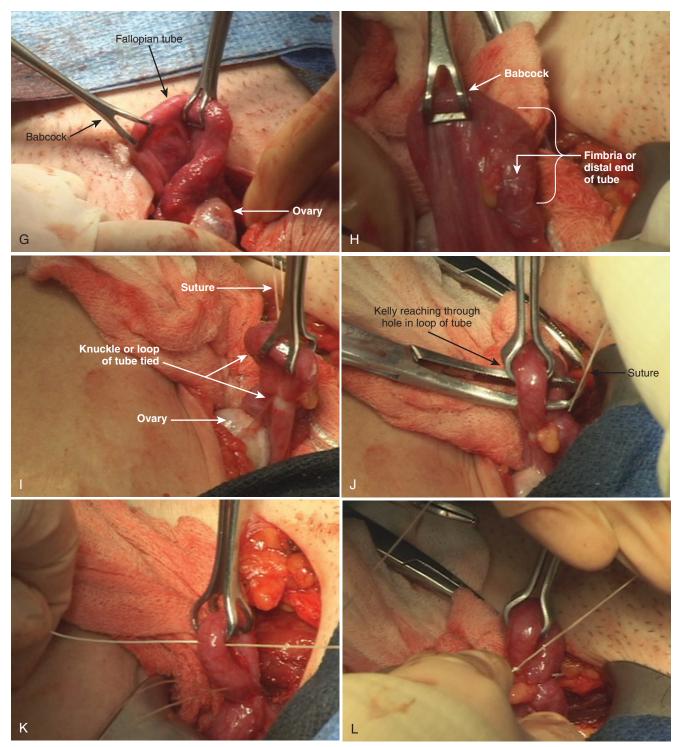

Figure 152-5, cont. G, The Babcock clamps are used in pairs to carefully retrieve the fallopian tube and follow it to the fimbriated end and ovary confirming its identification. H, Here a single Babcock clamp retracts the tube and demonstrates the widened fimbriated end. I, A loop of suture on a reel is used to tie off a loop of fallopian tube in the simple Pomeroy procedure. With the modified Pomeroy technique, a hemostat is passed through the center of the tied-off loop of fallopian tube and is used to guide suture material to individually tie off each side of the fallopian loop. J-L, Scissors are used to cut through the fallopian tube just above where the prior ties were seated. The incision is made at the crush mark left by the hemostats that were used to cross-clamp the tube.

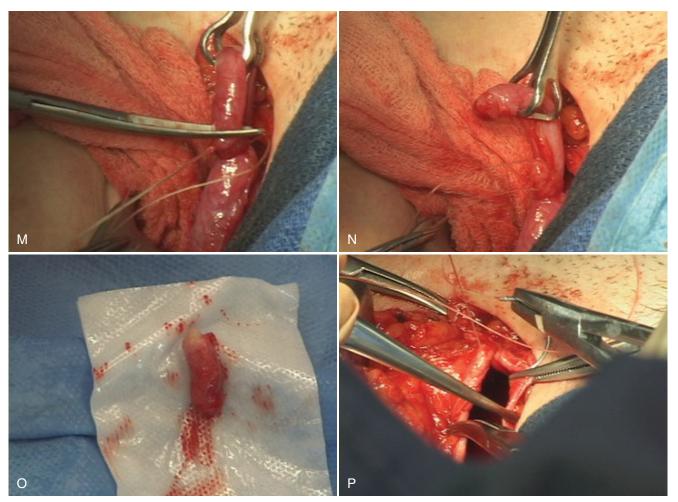

Figure 152-5, cont. M-O, The severed end is retracted and the opposite side of the loop is cut, freeing a 2- to 3-cm section of fallopian tube. P, It is critical to completely close the fascial layers identified by their white, thick, and tough nature.

Check in with the preoperative holding area. Is the patient's chart complete and informed consent form available and signed? Are the laboratory values within normal range? Does your patient have any questions? Is the family in the waiting room?

Tell the operating room scrub or float nurse what equipment and sutures you will need. Clarify the position that the patient will be placed in for the surgery (e.g., lithotomy, frog-legged, or standard supine position). Request a specific cleansing agent for patients who are allergic to iodine.

- Cleanse the vulva and vagina. A vaginal prep is necessary if the bladder is to be catheterized or a uterine manipulator is to be applied.
- 2. Drain the bladder. Perform a quick, gentle, straight catheterization to decompress a distended bladder from the operative field. Catheterization of the bladder is not universally performed. This is particularly true for patients under local anesthesia who can void sufficiently just before anesthesia. However, when the surgeon is new to this technique or when delay is anticipated in completing the abdominal entry (obesity, prior pelvic surgery, or infection), bladder injury is more likely. Draining the bladder helps reduce this risk. "Fluid blousing" at the time of general anesthesia induction is common, and the bladder can fill quickly.
- Apply the uterine manipulator (for interval minilaparotomy) as deemed necessary. Traditional devices include acorn or Hulka devices. Adaptations, such as CooperSurgical's uterine manipu-

lator (Fig. 152-4E), are easy to apply and are rarely traumatic. Many clinicians use manipulators routinely; others reserve them for anticipated problems with adequate exposure (abdominal obesity, prior pelvic surgery or infection, or retroversion or flexion of the uterus). Less-experienced surgeons will find them helpful. The patient must be in either the lithotomy or the frog-leg position, and general anesthesia is required.

- 4. Sterile gloves may be used without formal gowning for insertion of the uterine manipulator or for straight catheterization of the urinary bladder. In fact, it is advisable for the surgeon not to perform these procedures with the same formal gowning and gloving worn for the minilaparotomy, because contamination is likely when the patient is in the lithotomy position.
- Prepare and scrub the abdomen. Minilaparotomy should not be performed through pubic hair. Depending on patient pubic hair distribution, shaving a small strip of pubic hair over the operative site may be necessary.
- 6. After thorough surgical scrub and gowning, perform the procedure.
- 7. Apply surgical drapes as for abdominal surgery.
- 8. Locate the site for the incision. Palpate three fingerbreadths above the symphysis pubis. With one hand on the abdomen above the symphysis, move the uterine manipulator. Often the uterus can be felt with the abdominal hand, which offers reassurance that the incision will provide ready access to the uterus and adnexa. Using the skin scalpel with a no. 10 blade, make a transverse incision. There is no need to arc this incision. Often the linea nigra, the faint line demarcating the midline, can be visualized.

- The incision should be no more than 5 cm long, and often a smaller incision will suffice (see Fig. 152-5A).
- 9. Switch to the deep knife (new no. 10 blade) and progress through Scarpa's fascia (within the fat) until the rectus sheath is encountered (see Fig 152-5B). Often, once Scarpa's fascia is divided, the sub-Scarpa's fat can be brushed away with a sponge, using a wiping motion. Bleeders can be cauterized using the electrocoagulator. Do not tunnel the incision, especially in the obese abdomen; this can be prevented by ensuring that the subcutaneous fat has been divided all the way to both edges of the skin incision. The subcutaneous fat presents an excellent opportunity to test the power on the Bovie before entering the abdomen. The Bovie device should never be used for the first time on intra-abdominal tissue, in case the power is set dangerously high (see Fig. 152-5C).
- 10. Once the rectus fascia is identified by its dense, white fibrous appearance, make a small transverse incision on each side of the linea alba. Using a Metzenbaum scissors, carefully extend the fascial incision to the lateral margin of the skin incision and across the midline (see Fig. 152-5D). Place two Kelly clamps on the incised lower fascial edge and gently retract and elevate the fascia. Gently place the index finger (preferably) or the blunt end of the scalpel along the midline under the incised fascial edge, and gently roll it toward the lateral margins, freeing the sheath from the underlying rectus muscle. In the midline, the pyramidalis remains adherent; use the Metzenbaum scissors to carefully cut along the inferior linea alba, freeing the muscle and making more room. Apply Kelly clamps to the upper segment of the anterior rectus sheath, and free the underlying muscles in a similar fashion. You do not need to roll the index finger under the rectus sheath any further than the skin incision. Perforating vessels arise more laterally and can be ruptured. Carefully use cautery to control bleeding.
- 11. Using blunt dissection with the index finger or the blunt end of the knife, separate the rectus muscles from the transversalis fascia and peritoneum in the midline. A gentle rolling action of the index finger (or the blunt end of the scalpel) under each lateral band of rectus muscles ensures adequate room.
- 12. Using two Kelly clamps or pickups, opposing each other, lift the transversalis and peritoneum, thereby tenting these layers away from underlying abdominal structures. Using either the scalpel or Metzenbaum scissors, make a small buttonhole incision between the two clamps. This incision should be well above the symphysis pubis, favoring the cephalad (toward the umbilicus) portion of the wound to avoid the bladder. At this point, use a Kelly clamp to enter the small incision, and with a combination of blunt dissection and retraction of tissues, enter the abdomen. The key maneuver is to maintain this elevation of the incision edges to expose abdominal viscera. The obese abdomen may contain a significant amount of fat below the peritoneum, which requires special care when dissecting. It may be difficult to distinguish this tissue from omentum or mesenteric fat that may be adherent in the lower pelvis, especially in women with a history of abdominal surgery or infection. The peritoneal incision may be extended either transversely (preferred) or vertically. The edges of the incised peritoneum are grasped and elevated and the incision inspected to ensure the abdominal cavity has been entered (see Fig. 152-5E).
- 13. Place the small Richardson retractors, and with gently opposed and elevating retraction, lift the abdominal wall and inspect the abdominal cavity (see Fig. 152-5F). If the small intestine obscures the view, place the patient in the reverse Trendelenburg position (head down) to allow the bowel to gravitate cephalad out of view. Use a gauze pad rolled tightly on a ring clamp to brush the bowel and adnexal structures aside if they are obstructing the view. Using Babcock forceps, identify the adnexal structures. Once the fallopian tube is identified, use Babcock forceps to gently retract the tube until the ovary and fimbriated end are

- clearly identified (see Fig. 152-5G). Apply further slight traction on the Babcock to deliver the tube through the incision. Note the glistening white ovary, which assures the surgeon that the fallopian is being grasped (see Fig. 152-5H). Gentle traction is always advised because the tube can be adherent to vascular structures, which may bleed if torn. Use the uterine manipulator to help with visualization and exposure.
- 14. For the traditional Pomeroy tubal ligation technique, the Babcock forceps delivers a knuckle of tube, which is tied off with the 2-0 chromic suture. A second suture around this isolation knuckle of tube is often applied to achieve a tight, hemostatic construction before the knuckle of tube is excised (see Fig. 152-51).
- 15. For the modified Pomeroy tubal ligation procedure, carefully elevate the fallopian tube and identify a relatively avascular area of the mesosalpinx. Using a Kelly clamp to gently penetrate or the Bovie on "coag" (not "cutting") to avoid making too large of a hole, make a small hole through the mesosalpinx (see Fig. 152-5]). Then clamp the tube with a Kelly, placing one jaw through this hole and the other across the tube. Place another Kelly clamp 2 cm distal to the first one, isolating a segment of tube. Using a 2-0 chromic suture on a needle, place a stick-tie on the uterine side of the tube so that the suture encircles the tube next to the portion of the tube that connects to the uterus Kelly clamp (see Fig. 152-5K). Tag this tie (Kelly is placed on the suture to maintain control). Most surgeons place a second tie on the same side and cut (see Fig. 152-5L). Place a similar tie on the fimbriated side of the tube. Remove the Kelly clamps. Incise through each of the two crush marks made by the Kelly clamps that lie on the side of the encircling suture toward the excised piece of tube; remove the segment of the tube (see Figs. 152-5M and N). Place the cut segment of tube on a piece of Telfa, note right or left side, and submit for pathologic evaluation when the sugery is completed (see Fig 152-50). Lightly cauterize the exposed mesosalpinx if bleeding is observed. Cut the tags and repeat this procedure on the other tube. Current evidence supports the use of preemptive analgesia using infiltration of the incised skin and uterine tubes at cut ends with 0.5% bupivacaine. Postoperative pain, nausea, vomiting, and cramping were significantly lessened by this practice.
- 16. Perform a sponge count and, if it is correct, close the abdomen.
- 17. Identify and hold the edges of the *peritoneum* with Kelly clamps or pickups (see Fig. 152-5E). Use a running 3-0 chromic suture to *reapproximate* the cut edges. Identify and tag the fascial sheath edges with Kelly clamps. Close this sheath with a running 0 Dexon suture (see Fig. 152-5P). Palpate the closure to make sure there are no buttonhole defects in the fascial repair that could later manifest as incisional hernias. If there is more than 1 cm of subcutaneous fat, close Scarpa's fascia with interrupted 2-0 chromic sutures. The skin may be closed with staples or by running a subcuticular stitch of 3-0 chromic suture on a Keith needle.
- Cleanse the surgical site with normal saline and apply a gauze dressing.
- 19. Take the patient to the recovery room. She may be discharged when she is awake, is tolerating oral liquids, and is ambulatory. Send the tubal segments for routine pathologic examination; place them in separate bottles marked "right" and "left." Write a brief operative note in the chart. State any complications, blood loss, and other findings. Dictate a complete operative report immediately after surgery. The patient is generally seen in the office within 7 to 14 days or at any time a complication develops. Review the tubal histologic report.

#### **POSTPARTUM TUBAL LIGATION**

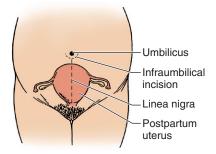

Postpartum tubal ligation (PTL) has many similarities to interval tubal ligation, but there are also major differences. Despite the

convenience, cost savings, and ultimate desires of the patient, PTL remains an elective surgery. Numerous *contraindications* include maternal fever, pregnancy-related hypertension, uncontrolled diabetes mellitus, and excessive blood loss. Concerns regarding the viability and health of the newborn must be considered as well. Women who must postpone their postpartum sterilization should be reassured that interval tubal ligation as early as 6 weeks after delivery is also an excellent method of sterilization surgery. PTL can readily be performed during cesarean section; however, never assume that PTL remains the patient's desire if the cesarean section was performed because of concern over the condition of the fetus. (See the sample patient education form online at www.expertconsult.com.)

#### **Technique**

Review the technique described earlier for interval tubal ligation.

- 1. PTL can often be performed with the same block (epidural, caudal) that was used during labor. If this is not desirable or possible, there are many advantages to allowing the patient to rest and recover from labor and to schedule the PTL procedure for the next morning. A repeat hemoglobin determination will be much more meaningful after equilibration of fluid, especially if there is concern over blood loss during delivery. This delay also allows more time to observe the condition of the newborn.
- The bladder should be drained either by having the patient void immediately before surgery or by straight catheterization (preferred method). Prepare the abdomen in the immediate umbilical area. Surgical scrub and draping are required.
- 3. Make a curved infraumbilical incision in the abdomen with the skin knife (no. 10 blade) (Fig. 152-6). Gentle inferior retraction on the abdominal skin at the time of this incision ensures that the scar will be close to or within the umbilical crater.
- 4. Carry the incision deeper with the deep knife (no. 10 blade). Once the skin and subcutaneous fat have been divided, enter the abdomen by favoring the inferior portion of the wound. (Dissecting through the substance of the umbilicus can be frustrating because tissue planes are not well defined.) Blunt dissection with Kelly clamps, which can probe and spread, is the preferred method for exploring and defining the portal of entry into the abdominal cavity. Some surgeons prefer to grasp each lateral side of the incision with towel clamps and elevate the entire incision away from underlying structures, such as the bowel and the uterus, when entering the peritoneum. Once the abdominal cavity is identified, the incision through the fascia and peritoneum can be extended, but it rarely needs to be longer than 4 to 5 cm.
- 5. Push the uterus gently to one side to rotate the adnexal structures into view. Use Babcock clamps to identify the fallopian tube, which in the postpartum period is typically swollen and engorged

**Figure 152-6** Postpartum tubal ligation by minilaparotomy requires a small transverse infraumbilical incision.

- compared with the nonpregnant state. Follow each tube until the fimbriated ends and ovaries are identified. Extremely gentle traction is warranted because vessels within the mesosalpinx can be huge and easily damaged by traction. Tears in these vessels can cause profound bleeding.
- 6. Once the tube has been identified clearly, perform a tubal ligation as described previously for the interval sterilization technique. If the mesosalpinx is extremely fragile, many clinicians prefer the more traditional modified Pomeroy technique. The loop, tie, and cut features of the Pomeroy render a quick hemostatic procedure that can minimize the traction injuries or raw cut edges of the mesosalpinx produced by other procedures. Remember that if the tube cannot be delivered through the incision for a tubal ligation procedure, clips may be applied to the correctly identified fallopian tube.
- 7. Close the abdomen in a layered fashion as previously described. With periumbilical incisions, it is sometimes difficult to clearly redefine the peritoneal edges for closure. However, closure of the fascia is crucial and time should be spent clearly identifying the edges of this layer for definitive suturing.
- 8. The patient is generally seen within 2 weeks of PTL. At this time, the histology report should be reviewed.

#### SAMPLE OPERATIVE REPORT

Identifying data: Patient is a 36-year-old white G2P2 who requests sterilization

Procedure performed: Minilaparotomy tubal ligation
Preoperative diagnosis: Elective permanent sterilization
Postoperative diagnosis: Bilateral tubal ligation

Estimated blood loss: Less than 5 mL

Complications: None

Operation performed: Modified Parkland excision of tubal segments

Surgeon: Dr. \_\_\_\_\_ Assistant: Dr.

Anesthesia: General with intubation

Procedure: The patient's preoperative examination and consent were obtained with prior office visit. The preoperative hematocrit and urinalysis are normal and the pregnancy test negative. The patient was identified by me prior to surgery. The patient was placed in the lithotomy position and a bimanual examination demonstrated a normal-sized, mobile uterus without abnormality. A Foley catheter was placed. The vulva and vagina were cleansed with Betadine, the cervix identified, and a Hulka intrauterine manipulator applied. The patient was then prepped and draped in the usual fashion. An incision site was identified three fingerbreadths above the pubic symphysis. A 4-cm transverse incision was performed and advanced, layer by layer, into the abdomen. Richardson retractors were used for exposure. The uterine manipulator was used to help identify the right tube. The tube was confirmed by inspecting its length distally to the right ovary. Babcock forceps were used to gently deliver a loop of tube through the abdominal incision. A relatively avascular window in the mesosalpinx was identified, the tube was cross-clamped on each side of this window. Stick-ties with 2-0 chromic suture were placed on each side of the clamps encircling the tube. Double ties were placed on the uterine side. A 2-cm section of the tube was removed and sent for pathologic evaluation. Minor bleeding was controlled with minimal coagulation. A similar procedure was performed for the left tube. The instrument and sponge count was correct and the incision was closed layer by layer with 2-0 chromic on the peritoneum, 0 Dexon suture on the fascia, 2-0 chromic on Scarpa's fascia, and a 3-0 chromic running subcuticular suture on the skin. The urine was noted to remain clear during and after the procedure. The Foley catheter and uterine manipulator were removed. The patient was extubated and taken to the recovery room in stable condition.

#### **COMMON ERRORS**

- Incomplete preoperative assessment overlooking medications (e.g., aspirin), prior pelvic surgeries (e.g., appendectomy), medical morbidities (e.g., poorly controlled diabetes).
- Failure to have a contraception plan to prevent pregnancy prior to the tubal ligation.
- Performing procedure when the patient's ability to make the decision for permanent sterilization is questioned (e.g., mentally challenged, unstable emotional or psychiatric status, consider legal and/or psychiatric consultation).
- 4. Attempting interval tubal ligation by minilaparotomy in women with significant abdominal obesity.
- 5. Failing to discuss alternatives to permanent sterilization.
- 6. Failing to review the postprocedure pathology report. Are there two segments of tube resected?

#### **COMPLICATIONS**

Minilaparotomy and laparoscopy have similar complication rates.

#### Major

- Major factors related to the development of complications include clinician inexperience, patient obesity, prior pelvic or abdominal surgery, and other medical problems such as diabetes mellitus, heart disease, asthma, bronchitis, and emphysema.
- Major complications occur in less than 2% of all procedures and may require prolonged hospitalization (0.3% requiring three or more nights in the hospital) or laparotomy (0.02% to 1.2% in large studies) to resolve complications.
- Delayed complications requiring readmission to the hospital occur after less than 1% of procedures.
- Female sterilization causes very few deaths (10 to 15 deaths per 500,000 procedures per year in the United States), and most are related to anesthetic complications (overdose or drug reaction), infection, and hemorrhage. Mortality rates from sterilization are far lower than with childbirth.
- Rare complications of tubal litigations include pregnancy (intrauterine and ectopic) and luteal phase pregnancy.

#### **Minor**

- Minilaparotomy appears to have a higher rate of minor complications (12% versus 7%) and a longer average operating time when compared with laparoscopy. Minilaparotomy convalescence appears to be slightly longer and more painful. Higher complication rates have been reported when laparoscopy is performed by inexperienced physicians.
- Minor minilaparotomy complications include wound infections, slight blood loss, uterine perforation by uterine manipulation instruments, and bladder injury. Most minor injury complications are immediately recognized and managed intraoperatively.
- Laparoscopy complications include those of minilaparotomy, as well as unique problems related to insertion of the instrument and gas insufflation of the abdomen. These complications include gas embolism, subcutaneous emphysema, and cardiac arrest.
   Vessel or organ laceration may occur. Open laparoscopy may make some of these complications less likely.
- Pain occurs after both minilaparotomy and laparoscopy. Chest and shoulder pain is common after laparoscopy and is caused by trapped gas under the diaphragm after insufflation of the abdomen. Most postprocedure and recovery pain can be managed with oral drug therapy, and narcotics are rarely necessary after the third postprocedural day.
- There is no compelling evidence that female sterilization causes menstrual cycles to change significantly; but abnormalities may persist if they existed before surgery. Among women who do

- experience menstrual changes, about half observe improvements and half experience irregular cycles or increased bleeding.
- Sterilized women do not appear to have different rates of pelvic inflammatory disease, cervicitis, hysterectomy, or D & C. Ovarian cancer may be diminished.
- Sterilized women are no more likely to experience severe psychiatric problems than unsterilized women.

#### POSTPROCEDURE MANAGEMENT

The surgeon is advised to check in on the recovery of the patient prior to leaving the hospital. Speak with family members in the waiting room, if available. Postoperative instructions can often be reviewed at this time. In most circumstances, patients can resume normal activities within 5 days following tubal ligation. Until then, heavy lifting and vigorous activities, such as jogging or weight training, should be postponed for about 5 days or until comfortable. Baths or hot tubs should be avoided for 10 days. Showers are recommended. A postoperative visit in the office in 7 to 10 days is advised. At this time, recovery experience, tubal pathology report, and other questions can be explored.

#### POSTPROCEDURE PATIENT EDUCATION

Give the patient postprocedure instructions and inform the family of any follow-up instructions. (See the sample patient education form online at www.expertconsult.com.)

#### INTERPRETATION OF PATHOLOGY RESULTS

The surgeon must review the pathology report, which is generally available within 7 to 14 days following the procedure. Two segments of fallopian tube with evidence of complete resection of their diameter should be obtained. Failure to document two segments requires that the patient be informed and appropriate steps be initiated to prevent pregnancy and allow time for evaluation. In most instances, waiting 8 weeks to allow for internal healing and performance of a hysterosalpingogram will help assess whether or not both tubes are indeed blocked or, in fact, whether the wrong structures, such as the round or ovarian ligaments, were removed. Avoid performing the hysterosalpingogram prior to 8 weeks to allow for adequate healing. Each patient requires individual management in this circumstance. Some may opt for repeat procedures while others will reconsider other options of contraception.

### **PESSARIES**

Sandra M. Sulik

Historically, pessaries have been used to correct pelvic floor deformities and dysfunctions and symptoms associated with genital prolapse, uterine retrodisplacement, and cervical incompetence in women. In addition to hanging women by their heels, physicians as early as Hippocrates reported the use of half a pomegranate soaked in vinegar in the vagina for women with prolapse! In 1860, Hugh Lenox Hodge, Professor of Gynecology at the University of Pennsylvania, designed a pessary using Goodyear's newly patented vulcanized rubber. Since that time, technological advances in composition and a wide variety of sizes and shapes now make fitting pessaries an art (Fig. 153-1).

#### **INDICATIONS**

- Stress urinary incontinence (including athletic stress urinary incontinence)
- Uterine prolapse
- Vaginal vault prolapse
- Uterine retrodisplacement
- Pelvic relaxation
- Cvstocele
- Enterocele
- Rectocele
- Poor surgical candidates with significant symptoms
- Prophylactic, postoperatively
- Preoperative diagnostic aid while awaiting surgery
- Cervical incompetence (proposed indication)

Indications for pessary use include reduction of pelvic organ prolapse and stress urinary incontinence. Preoperative use of pessaries as a diagnostic tool for any of the preceding indications can be helpful to estimate the amount of normal function that may be restored after surgery. A pessary can also help determine if the patient will develop incontinence once the prolapse is surgically corrected. Although surgery generally produces a more permanent cure, a pessary may be the treatment of choice for women who are poor surgical candidates, who want to postpone surgery indefinitely, or who prefer a nonsurgical treatment option. Pessaries may also be used postoperatively in women at risk for recurrent prolapse. Use of the pessary has been proposed as an alternative to cerclage to prevent preterm delivery. Only limited data support this indication, and it has not achieved widespread use.

#### **CONTRAINDICATIONS**

- Noncompliant patient
- Impaired mental capacity leading to inability to follow up
- Persistant vaginal ulceration/erosions (relative)
- Active vaginitis (relative)

- Any pelvic infections or lacerations (relative)
- Severe atrophic changes (relative)
- Lack of manual dexterity

Active vaginitis including atrophic changes and vaginal ulcerations should be treated and resolved before pessary use. Although ulcerations are generally considered a contraindication, when they are a direct result of an exteriorized prolapse, a pessary may prevent further injury and promote healing. Severe atrophic changes are a contraindication to immediate pessary use; however, once the vagina is re-estrogenized, the pessary may be used. The woman using a pessary must be mentally and physically capable of using the device as recommended and able to return for appropriate follow-up.

#### **EQUIPMENT AND SUPPLIES**

Approximately 75% of women with prolapse can be successfully fitted with a pessary. Unsuccessful fitting is more likely with a shorter vagina (<7 cm) or a wide introitus (>4 fingerbreadths), higher parity, and previous hysterectomy. Most women with pessaries are satisfied and experience improvement in their symptoms.

There are two major types of pessaries: support and space filling. Most pessaries are made of silicone, some from rubber (avoid in latex allergic patients), and a few from plastic. Silicone has the advantage of being nonallergenic, and it does not absorb odors or secretions and is pliable and soft, so it is well tolerated.

A properly fitted pessary should be comfortable for the patient; it should remain in place while walking and standing, and during provocative maneuvers (e.g., coughing, standing, Valsalva's maneuver); and it should not interfere with bladder and bowel function. The pessary should fill the vagina, but should easily admit the examiner's finger between the pessary and the vaginal wall.

#### **PESSARY SELECTION**

Pessaries are available in a wide range of sizes and shapes, each with a specific indication and function. *Selection depends on anatomy, symptomatology, and the overall goal of treatment.* Identifying the best choice is often a trial-and-error process; clinicians and patients should not be discouraged if the first selection is unsuccessful. *The most commonly prescribed pessaries are the ring, the Gellhorn and the donut.* For the novice starting to fit pessaries for the first time, obtaining fitting kits and samples of the most commonly used pessaries from the various companies may lessen the difficulty of pessary fitting.

Pessaries are made with several modifications on the same theme. For example, the ring pessary has a version "with support," which has a silicone web across the central opening. This "supports" the bladder, effectively reducing a mild to moderate cystocele. The "ring

Figure 153-1 Various type of pessaries. I, Hodge with knob; 2, Risser; 3, Smith; 4, Hodge with support; 5, Hodge; 6, tandem cube; 7, cube; 8, Hodge with support and knob; 9, Regula; 10, Gehrung; 11, Gehrung with knob; 12, Gellhorn flexible; 13, Gellhorn rigid (acrylic silicone); 14, ring with support; 15, ring with knob; 16, ring with knob and support; 17, Inflatoball; 18, Shaatz; 19, incontinence dish with support; 20, incontinence ring; 21, incontinence dish; 22, donut; 23, ring. (Courtesy of CooperSurgical, Inc., Trumbull, CT.)

with knob" has a bulbous portion that is placed retropubically (at the pubic notch) to restore the urethral-vesical (U-V) angle and increase urethral closing pressure. The addition of the "knob" is for stress urinary incontinence from a hypermobile U-V angle. Some devices have both modifications.

#### **PESSARY TYPES BY INDICATION**

- Stress incontinence: ring with knob, Hodge, Hodge with knob, Smith, Risser, incontinence ring, incontinence dish, Mar-Land, Gehrung with knob (Fig. 153-2)
- Preoperative evaluation for Burch procedure for stress incontinence: Hodge, Risser, and Hodge with support
- Uterine retrodisplacement: Smith, Risser, and Hodge
- Uterine prolapse, first or second degree: ring, ring with support, Shaatz, Regula, Oval, Smith, Risser, Hodge
- Uterine or vaginal vault prolapse, third or fourth degree: donut, Inflatoball, cube, tandem cube, Gellhorn (not well suited for severe vaginal prolapse)
- Stress incontinence with cystocele, first or second degree: ring with support (with or without knob) incontinence dish with support, Gehrung with knob, and Hodge (with/without support, with/ without knob), Mar-Land with support (Fig. 153-3)

**Figure 153-2** Stress urinary incontinence pessaries (made with silicone). I, Hodge with knob; 2, Regula; 3, Gehrung; 4, Gelhorn flexible; 5, tandem cube; 6, donut; 7, ring; 8, incontinence dish; 9, Shaatz. (Courtesy of Cooper-Surgical, Inc., Trumbull, CT.)

**Figure 153-3** Mar-Land pessaries with (*left*) and without (*right*) support. (Courtesy of Coloplast Corporation [formerly Mentor Corporation], Minneapolis, MN.)

- Stress incontinence with uterine prolapse, first or second degree: ring, incontinence ring, ring with support and knob, incontinence dish (with/without support), Mar-Land, Mar-Land with support, Hodge (with/without support, with/without knob and support)
- Cystocele: Gehrung, Gehrung with knob, ring with support, Gellhorn, donut, Inflatoball, cube, and tandem cube
- Enterocele: Gellhorn, Gehrung, donut, Inflatoball, cube, tandem cube
- Rectocele: Gellhorn, Gehrung, donut, Inflatoball, cube, tandem cube
- Incompetent cervix: Hodge

#### **PROCEDURE**

#### **Fitting Pessaries**

Pessaries are fit by trial and error. Proper fitting often requires multiple sizes and or styles. Fitting pessaries can be done from fitting kits obtained from the manufacturer or by stocking multiple sizes and fitting the pessary from stock. Fitting kits are available from the two largest manufacturers of pessaries in the United States: Milex and Coloplast Corporation. Milex has kits for the ring, the Gellhorn, the cube, and the Gehrung pessaries. The Coloplast Corporation has a kit for fitting the ring pessary with a conversion chart for converting the size of the ring pessary to other types it manufactures. Conversions of pessary sizes are difficult, however. The totally different shape of each pessary and whether the pessary fits in front of the cervix (e.g., the Gellhorn, donut, or cube), behind the cervix (e.g., the lever pessaries), or over the cervix (e.g., the Gehrung) precludes simple conversions. The manufacturer should be contacted for product information and obtaining pessary fitting kits.

When fitting a pessary for incontinence, it is best for the patient to have a full bladder. If fitting for prolapse, the patient should empty her bladder before the fitting process. Once the correct pessary has been determined, the patient should be able to void comfortably with the pessary in place before she leaves the office. Ideally, the patient should insert and remove the pessary on a daily basis. Women can remove the pessary at bedtime, wash it with soap and water, and then replace it in the morning. If daily changing is too cumbersome, a schedule of twice weekly can be used. In this setting, an early follow-up should be arranged to assess the vaginal walls and ensure no erosions are developing. If the patient is unable to remove her pessary regularly, most pessaries can be left in place and removed on a monthly basis, cleaned, and reinserted by the clinician. On the other hand, the cube and Inflatoball pessaries must be removed daily. An applicatorful of an acidifying gel such as Trimo-San inserted into the vagina two or three times per week should be recommended to help decrease the amount and odor of vaginal discharge.

Prior to fitting the pessary, the vagina should be inspected for estrogen status, erythema, erosions, and ulcerations. A Papanicolaou (Pap) smear should be obtained if indicated. *Determining pessary size for all round pessaries is similar to fitting a contraceptive diaphragm* (see Chapter 130, Barrier Contraceptives: Cervical Caps, Condoms, and

Diaphragms). A rough estimate of length of the vagina is determined by measuring the distance from the posterior fornix or vaginal apex to the symphysis pubis. The second and third fingers are placed in the vagina with the third finger in the posterior fornix. The depth of insertion is marked on the second finger. The distance between the tip of the third finger and the mark on the second finger approximates vaginal depth (see Figure 130-5 in Chapter 130, Barrier Contraceptives: Cervical Caps, Condoms, and Diaphragms). This is also a good opportunity to evaluate pelvic floor strength and teach the patient how to do Kegel exercises. Several pessary sizes can be tried to find the proper fit.

Once the appropriate pessary is found, the patient should be reexamined after performing provocative maneuvers. Provocative maneuvers include coughing, standing, sitting, walking, squatting, and Valsalva's maneuver. Then the patient should try to void. If the patient is unable to void comfortably or if discomfort is noted during these maneuvers, the next smaller size of pessary should be tried. If the pessary has shifted position or falls out after these maneuvers, a larger size or different pessary should be tried.

#### **USE OF SPECIFIC PESSARIES**

Uses for specific pessaries are listed in Table 153-1.

#### **COMPLICATIONS**

- Vaginitis
- Vaginal erosion or ulceration
- Discomfort
- Obstructed defecation and/or urination
- Impaction of the pessary

It is normal for the patient to experience an increase in vaginal discharge. However, odor, itching, change in color of discharge, or bleeding should be reported to the health care provider. Use of vaginal estrogen with pessaries generally prevents vaginal erosion and ulceration. Many health care providers overlook the importance of estrogen in maintaining the acid pH balance necessary to prevent vaginitis. The vagina should be re-estrogenized by using vaginal estrogen cream, 1 g every other night for 1 month, then two to three times per week thereafter. Alternating a pH-adjusted vaginal gel (e.g., Trimo-San gel, half applicator, two or three times per week) with the estrogen cream is beneficial as well if the pessary is left in place and not removed nightly. In addition to atrophic changes, ulcerations may be associated with a device that is too large or not removed on a regular basis. Discomfort is usually associated with anterior displacement during Valsalva's maneuver or a device that is too large. If anterior displacement is noted, the patient should push the pessary further into the vagina. If that does not alleviate the discomfort, a smaller size should be tried. Obstruction of defecation should be promptly reported to the provider. Removal of the pessary should resolve the problem, and delay in removal may lead to obstipation. Obstruction of urination should be uncommon if voiding was performed in the office with the device in place. A smaller pessary should resolve the problem. Impaction of the device is rare and typically associated with "forgotten pessaries." A reminder system such as a tickler file will help to alleviate this problem and ensure appropriate follow-up.

#### POSTPROCEDURE MANAGEMENT

#### **Pessary Care**

Patients should remove the pessary and wash it with warm, soapy water. Soap with deodorants, perfumes, or detergents should not be used. Autoclaving (15 lb pressure for 15 minutes) is the recommended method of sterilization for pessaries from the fitting sets between fittings.

#### Follow-up Care

Ideally, the pessary should be removed nightly, and cleaned and replaced the next morning. Realistically, women are reluctant to comply with such frequency. In many cases, pessaries have been left in the vagina for months at a time without complication. (The cube and tandem cube and Inflatoball must be removed nightly because there are no holes for drainage.) The final decision is left to the health care provider and the patient and should be based on several factors: the patient's mental and physical capacity to insert and remove the device and willingness to do so on a regular basis; the health of the vaginal mucosa; the potential for complications; how well the device fits; and the patient's ability to comply with follow-up visits.

In general, reevaluate the patient 1 week after the initial fitting, and then at 1 month and 3 months later. At a minimum, the patient should be seen every 6 months thereafter. Patients unable to care for the device themselves should be seen at least every 2 to 3 months. At each visit the patient should be questioned about bowel and bladder function, symptoms associated with vaginitis, vaginal bleeding, and problems with insertion and removal. The device should be removed and the vaginal mucosa should be inspected for erythema, ulceration, laceration, and estrogen status. The device may be cleaned and reinserted if there are no complications. The pessary is a foreign body in the vagina. Inspection of the vaginal vault at regular intervals seems prudent and warranted.

#### TIPS

The following are anecdotal helpful hints and not manufacturers' recommendations.

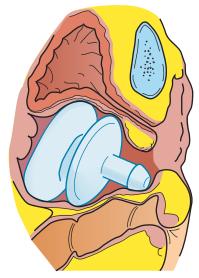

- Diaphragms: A diaphragm can be very effective for mild degrees of prolapse or incontinence.
- Stay relaxed for device removal: The patient should keep the pelvic floor muscles relaxed and even perform a gentle Valsalva maneuver to assist with removal.
- Estrogen: Regular use of vaginal estrogen cream should be strongly encouraged. The Estring may also be used with several of the pessaries.
- Double pessaries: A small donut coupled with a Gellhorn pessary
  may be useful for patients with excessive redundant tissue. The
  donut is placed closest to the cervix with the Gellhorn facing out
  into the vagina. The stem of the Gellhorn does not fit through
  the hole in the donut (Fig. 153-4).
- Pelvic floor muscle exercises/Kegel exercises: Ongoing performance of Kegel exercises is important to maintain and improve pelvic floor tone and should be encouraged with all follow-up visits. If a patient is unable to perform Kegel exercises on her own, useful patient devices include Kegel Kones (a set of six weighted devices, which get progressively smaller and heavier). The Kegel Exersizer is an intravaginal device that measures intravaginal pressure. The cone-shaped device has an approximately 2-foot flexible hose to transmit the pressure to a gauge to give the patient positive feedback with a proper perineal (Kegel) contraction. Some physical therapy departments have assisted patients with proper technique for Kegel exercises by using this type of device.
- A woman with very little or no vaginal muscle tonicity or marked vaginal wall prolapse may have difficulty even retaining a donut or a Gellhorn pessary. In such cases the cube pessary is indicated.
- Sexual activity: Some pessaries can be left in place during intercourse. Most often, women remove the pessary prior to engaging in sexual activity. A ring pessary is an effective device for women who leak urine with orgasm.
- Pessaries and x-rays: Some pessaries contain wire coils; these pessaries must be removed before an x-ray or magnetic resonance imaging. The face page of each pessary instructional brochure indicates whether the pessary contains metal. An instructional brochure is enclosed with each pessary.

TABLE 153-1 Us	Use of Pessaries						
Condition	Pessary	Common Sizes	Features	Company	Insertion	Removal	Other Pessaries to Try
First-degree and Second-degree prolapse	Ring	0–13, 2–7 most common	One of the easiest to use, requires a well-defined pubic notch for pessary to rest	Milex, EvaCare	The device is hinged and will fold in only one direction; once inserted rotate 90 degrees to decrease chance of expulsion with Valsalva.	Insert the index finger into the notch and rotate the hinge anteriorly; pull down and out.	Gelhorn, donut, Gehrung, Shaatz, oval, Inflatoball, Regula
	Ring with support	0–13, 3–5 most common	Supports mild cystocele as well	Milex, EvaCare	Insert same as ring	Same as for ring	Same as for ring
	Shaatz	1½ inches to 3½ inches, most common 2¼ inches to 3 inches to 3 inches	Utilizes levators for support, especially effective in patients where ring pessary does not stay in place	Milex, EvaCare	Compress the sides and turn the device parallel to the introitus, advance until it rests against cervix; insert with concave surface facing up.	Hook the index finger in the center hole; bring device down to introitus; pull down and out.	Gellhorn, Gehrung, ring with support, oval, donut
	Regula	Most common 2-8	The pressure exerted by the prolapsed uterus/cervix on the flexible anatomically adjusting arch or bridge of the regula automatically spreads the heels outward, thereby helping to prevent the expulsion of the pessary. The patient should be forewarned that it may be necessary for her to be refit several times.	× ≡ EX	The flexibility of the bridge, which alters the support dimensions of the pessary, must be balanced with the size of the patient's vaginal vault and the degree of uterine prolapse.	Reach in, grasp pessary and pull down toward introitus.	Gelhorn, donut, Gehrung, Shaatz, oval, Inflatoball
	Oval	Most common 1–9	Designed specifically to fit a narrow vagnal vault. Works extremely well in women with a prior history of vaginal surgery that resulted in scarring, and in some cases palpable sutures from anterior repair or bladder suspension procedures.	EvaCare	Fold pessary at flexible joint; insert and rotate to fit.	Reach in, grasp pessary and pull down toward introitus.	
Third-degree prolapse	Donut	2 inches to 3¾ inches most common, also 2 ½ to 3 ¼ inches	The most commonly used pessary. A space-occupying device that is useful in patients with excessive redundant tissue; works well in a vaginal vault with little or no support; most commonly used in older, postmenopausal women; works well for vaginal prolapse also.	Milex, EvaCare	Turn the device parallel to the introitus; exert pressure posteriorly, and advance until it is fully intravaginal; then rotate until the pessary is transverse and up against the cervix.	Hook the index finger in the center hole, bring device down to introitus; pull down and out.	Gellhom, Inflatoball, Gehrung

	Other Pessaries Removal to Try	sul .	suction; pull disk towards introitus and remove. Can use a barber pole action. Can inject a small amount of water or saline into the hole in the knob to help release the suction.	₩ <del>\</del>	suction; pull disk towards introitus and remove. Can use a parber pole action. Can inject a small amount of water or saline into the hole in the knob to help release the suction.  The string is used to help locate the pessary; it should not be used to pull not be used to pull not be used to pull of the suction should be released by squeezing the walls of the cube and then pulling the device in a downward fashion.  The pessary must be removed and cleaned daily. Regular use of estrogen cream in postmenopausal women is recommended.  Same as for cube
		Insigning are errorly iin push		d insert it	Ė S
oany In	Fo	until the entire disk is within the vagina; then turn and push the knob upwards toward the cervix.	Care		Insert with larger cube
Company ginal Milex, EvaCare tors.	Σ	thes be ylic se	her Milex, ause EvaCare d the	pu	and Milex s are
	Features	Requires a relatively capacious vaginal vault so that the base is broad enough to rest above the levators. The stem functions to stabilize the device in the vagina and facilitates removal. A shorter stem is available by special order. Can be ordered as rigid silicone or acrylic for severe prolapse. Not well suited for severe vaginal prolapse because the walls can prolapse around the pessary.	May be used in women with either a small or a large introitus because of its malleability. Has no area for drainage, must be removed nightly. Support is achieved by creating negative pressure on the wainal walls. Attorbir changes	vaginat wats. An opine changes increase the risk of ulceration and erosion.	Try if single cube does not work. Can be used in young work. Can be used in young women who experience stress incontinence with vigorous exercise when other pessaries are ineffective.
	Common Sizes	$1\frac{1}{2}$ to $3\frac{1}{2}$ inches, most common $2\frac{1}{4}$ to $3$ inches	0–7, most common 2–5		The larger cube is 2 sizes bigger than the small one. 2/0-7/5, most common
	Pessary	Gellhorn	Cube		Tandem cube
	Condition	Third-degree prolapse—cont.			

TABLE 153-1	Use of Pessaries—cont.	.:					
Condition	Pessary	Common Sizes	Features	Company	Insertion	Removal	Other Pessaries to Try
Incontinence pessaries	Incontinence ring (ring with knob)	0-10, 2-7 most common sizes	The device stabilizes the bladder base and increases urethral functional length and dosure pressure.	<u>A</u> ile ×	Compress the ring and insert with the knob in the anterior direction; knob fits just below pubic notch.	Grasp, and pull in a downward fashion.	Incontinence dish, ring with support and knob, Gehrung with/without knob, Hodge, Smith, Risser, Mar-Land
	Incontinence dish with/without support	55–85 mm, most common 60–75 mm (Milex brand), 0–7 (EvaCare brand)	Continence is restored by stablizing the bladder base, increasing urethral dosure pressure, and lengthening the functional urethra. It also offers support to an accompanying mild prolapse.	Milex, EvaCare	Compress the device and turn it parallel to the introitus. Rotate the device once it is intravaginal so that the heel is posterior to the cervix and the knob is retropubic.	Hook the index finger and pull down and out or losert index finger between the device and the symphysis; grasp between the finger and thumb, and pull down and out.	Hodge with/ without support, Mar-Land with support
	Mar-Land with/without support	2–8, most common 2–5	An adaptation of the ring pessary; has a round Silastic base with a half-moon support that fits retropubically	EvaCare	Compress the device and turn it parallel to the introitus. Rotate the device once it is intravaginal so that the heel is in the vault or posterior formix and the arch is positioned retropubically. May also be inserted by folding the pessary in half so that the back ring collapses the supportive sling. The folded pessary should be in a crescent shape and inserted by directing the cresecent shape downward; advance it until the device is fully intravaginal and the supportive sling is retropubic.	Hook the device with the index finger and rotate parallel while pulling down and out.	Hodge with/ without support, incontinence ring, incontinence dish.
	Gehrung with/without knob	0–9, most common sizes 2–5	"Saddle pessary"; manually shapeable, which allows for fit in most women. Support derived from the lateral remnants of the elevator sling. Gehrung with knob useful for cystocele coupled with stress incontinence.	Milex	Compress the sides of the device and turn it parallel to the introitus. Insert the left heel and advance until the device is fully intravaginal; rotate the anterior arch forward so that the cystocele rests on the bridge. The heels of the pessary rest on the vaginal floor.	Push the anterior arch posteriorly toward the rectum; grasp the lateral heel and fold to remove.	Hodge with/ without support, incontinence ring, incontinence dish with/ without support

TABLE 153-1	Use of Pessaries—cont.	ني					
Condition	Pessary	Common Sizes	Features	Company	Insertion	Removal	Other Pessaries to Try
Incontinence pessaries—cont.	Hodge with/without knob Hodge with/without support	0-9, most common size 2-5	Originally designed for uterine retrodisplacement, Hodge with knob restores continence by stabilizing the bladder base and increasing urethral dosure pressure and functional urethral length. Designed for patients with a shallow pubic notch. Can be used for patients with a shallow pubic notch. Can be used for patients with stress incontinence associated with urethral hypermobility, first- and second-degree prolapse, and uterine retrodisplacement. The Hodge can be used as a test of effectiveness of the Burch procedure for stress incontinence. Has also been used for treatment of incompetent cervix with or without cerdage.	∑ ≅ X	Compress the sides and insert the rounded end into the vagina; direct the heel into the vault or posterior fornix and position the anterior portion retropubically. The device should fit snugly, should not rotate, and should remain retropubic.	Hook the device with the index finger to fold it, and pull the device down and out.	Incontinence ring, incontinence dish, or Mar-Land
Uterine retrodisplacement	Smith (designed for a patient with a well-defined pubic notch) Risser (designed for a patient with a shallow pubic notch, has a larger weight-bearing zone to support the vaginal aspect of the pubis)	Smith: 0–8, 2–5 most common Risser: 0–9, 2–5 most common	Can be used for a number of other conditions, including dysmenorrhea when no other cause except uterine retroversion is noted, infertility if retroversion is considered the cause, and backache if attributed to uterine retroversion.	Milex X	Insertion same as for Hodge	Same as for Hodge	Hodge with/ without support/knob, Mar-Land, inconfinence ring, or inconfinence dish

**Figure 153-4** Double pessaries in place. The donut pessary is inserted first, and the Gellhorn pessary (stem out) is inserted second. (Redrawn from Myers DL, Lasala CA, Murphy JA: Instruments and methods: Double pessary used in grade 4 uterine and vaginal prolapse. Obstet Gynecol 91:1019, 1998.)

#### **CONCLUSION**

Although surgical repair remains the treatment of choice for many urogynecologic dysfunctions, pessaries are a viable option for a variety of situations. Pessaries are useful for both the rising elderly population but also for younger active women who wish to maintain their activities without the discomfort of prolapse or leaking of urine.

#### **CPT/BILLING CODES**

The pessary cost is considered a supply. It should be billed to the local Medicare Part B carrier or the patient's insurance company.

57160 Pessary fitting and insertion

An E/M code may also be billed with a -25 modifier depending on documented examination and decision-making complexity. Only the E/M code is to be used when the patient comes in for removal and cleaning and reinsertion.

A4561 Rubber pessaries or intravaginal devices

A4562 Nonrubber pessaries or intravaginal devices

In some areas, the alternative for Part B providers is to write a prescription for the device, have the patient fill the prescription at a local pharmacy or medical supply store, and return with the pessary for insertion. Place of service is the home of the patient.

#### **ICD-9-CM DIAGNOSTIC CODES**

618.00 Vaginal wall prolapse, unspecified (w/o uterine prolapse)

618.01 Cystocele midline or lateral (w/o prolapse)

618.04 Rectocele (w/o uterine prolapse)

618.1 Uterine prolapse (w/o vaginal wall prolapse)

618.2 Uterovaginal prolapse, incomplete

618.3 Uterovaginal prolapse, complete

618.4 Uterovaginal prolapse, unspecified

618.5 Posthysterectomy vault prolapse

618.6 Enterocele, vaginal

618.9 Unspecified genital prolapse

618.81 Incompetence or weakening of pubocervical tissue

618.82 Incompetence or weakening of rectovaginal tissue

618.83 Pelvic muscle wasting

621.6 Retroflexed uterus, symptomatic

625.6 Incontinence, stress

654.5 Cervical incompetence in pregnancy

## POSTCOITAL TEST (SIMS-HUHNER TEST)

Julie M. Sicilia

The postcoital test (PCT) is an evaluation of the survival and motility of sperm in the cervical mucus. The PCT is a way of detecting if sperm are present in the ejaculate and cervical mucus; it is not a diagnostic test for cervical factor infertility. The PCT should be used in conjunction with semen analysis, not as a substitute for it. Result validity has been questioned because of the lack of reproducibility and universal standards for obtaining and interpreting samples with the PCT. The PCT was previously a routine test in the infertility evaluation. A 1998 randomized controlled trial concluded that routine PCT for infertile couples increased the amount of testing but did not increase the pregnancy rate for the couples. Currently, the PCT is used only for guiding treatment decisions for couples with certain indications.

## **INDICATIONS**

- Investigation of the sperm and cervical mucus interaction
- Monitoring the cervical mucus during the first ovulatory cycle of treatment with clomiphene citrate for couples planning timed intercourse infertility treatment
- To assist in deciding if a couple is a candidate for expectant management versus aggressive therapy (intrauterine insemination [IUI] or in vitro fertilization [IVF]) with suspected cervical factor infertility

## **CONTRAINDICATIONS**

- Any condition that would preclude unprotected sexual intercourse followed by examination and sampling of the cervix
- Active vaginal infection

## **EQUIPMENT**

- Nonsterile examination gloves
- Vaginal speculum (no lubricant) and swabs
- Tuberculin syringe with cap
- Ring forceps
- Microscope, slides, and coverslips
- Plastic endometrial aspirator (optional)

## PREPROCEDURE PATIENT EDUCATION

One month prior to PCT, have patient start measuring basal body temperature (BBT) or urinary luteinizing hormone (LH) ovulation testing. Review the BBT or LH graphs to determine the proper timing of intercourse. Have the patient watch for clear cervical mucus (more estrogenic). (See Chapter 150, Fertility Awareness–Based Methods of Contraception [Natural Family Planning].) The PCT should be performed as near as possible to ovulation. The test is usually performed on day 12 to 14 of an ideal 28-day cycle.

- Instruct the couple to abstain from intercourse or masturbation for 48 hours before the test. Before performing the PCT, determine that the BBT is in accord with the proper timing of the menstrual cycle for the performance of the test. Nothing (lubricants, medications, douches, etc.) should be placed in the vagina for 24 hours prior to the test and up to the time of the PCT.
- Instruct the patient to come to the office 6 to 10 hours after intercourse.

## **PROCEDURE**

- 1. Place the patient in the dorsal lithotomy position. Insert a vaginal speculum (without lubricant) and visualize the cervix. Gently wipe the cervix with a vaginal swab.
- 2. Insert a tuberculin syringe (without the needle) into the endocervical canal and retract the plunger to draw the mucus into the syringe (collect at least 0.2 mL of mucus). An endometrial aspirator may make this collection easier in some patients. Place the syringe cap over the hub of the syringe once the sample is obtained so that the mucus will be stored in an airtight container until it is ready for processing.
- 3. Record the amount and clarity of the mucus.
- 4. Record the degree of stretchability (i.e., spinnbarkeit) of the mucus. A ring forceps may be used to grasp the mucus at the cervical os to measure the mucus stretch as the forceps is removed from the vagina. The mucus can also be placed between the index finger and thumb with the stretch determined as the fingers are drawn apart. A normal mucus stretch greater than 5 to 10 cm is indicative of a high estrogenic state. A spinnbarkeit of less than 3 cm indicates a low likelihood that sperm could penetrate through the mucus and indicates an unfavorable situation for fertilization.
- 5. Place a drop of the mucus from the syringe on a glass slide and immediately place a coverslip over the sample. Examine the cervical mucus under low power for the presence of sperm and other components, such as trichomonads, leukocytes, squamous cells, or Candida. Make a note of the number of sperm. Examine the specimen under high power. The number of sperm in at least five different fields should be averaged. Record an average number or range of numbers of sperm present. Note whether the sperm are mobile, whether they have normal or abnormal morphology, and, if possible, whether they exhibit forward progression. For a normal study, if specimens are examined 6 to 10 hours after intercourse, there should be an average of at least 5 to 10 actively motile sperm per high-power field. Actively moving sperm are facilitated by the presence of optimal cervical mucus. A decrease in the quality of the cervical mucus and an increase in viscosity and cellularity caused by rising progesterone levels after ovulation impair sperm survival. The presence of ferning, increased elasticity, and decreased viscosity of the cervical mucus is an indirect indication of estrogen production and ovulation.

## **COMMON ERRORS**

The primary cause of an inconclusive or abnormal PCT is failure to accurately time the test. PCTs are also usually abnormal in anovulatory cycles. If the initial PCT yields poor results, a second test should be performed 1 to 3 hours after intercourse in the next menstrual cycle month.

## **COMPLICATIONS**

Falsely abnormal results can result from poor timing of the menstrual cycle, poor mucus quality because of infection, coital positions not favoring vaginal sperm retention, and low semen volume or low numbers of sperm. Although a normal PCT is encouraging, an inadequate test does not necessarily preclude fertilization.

## POSTPROCEDURE PATIENT EDUCATION

If the test is inconclusive or abnormal, the PCT may be repeated. IUI or IVF, although expensive, are readily available in the United States. IUI and IVF bypass cervical mucus/sperm interaction abnormalities and should be offered to couples as a treatment option when indicated, especially in couples wanting multiple pregnancies or older couples (>35 years old).

## INTERPRETATION OF RESULTS

A normal result is 5 or more motile sperm per high power field. The mucus should also be thin, clear, and have a stretch of more than  $5\ \mathrm{cm}$ .

## **CPT/BILLING CODE**

89300 Semen analysis; presence or motility (or both) of sperm, including Huhner test

## **ICD-9-CM DIAGNOSTIC CODES**

606.0 Infertility, male (due to azoospermia)

606.1 Oligospermia

606.9 Infertility, male, unspecified

628.4 Infertility, female (due to cervical origin)

628.9 Infertility, female (of unspecified origin)

## TREATMENT OF NONCERVICAL CONDYLOMATA ACUMINATA

Harris Mones

The increased incidence of human papillomavirus (HPV) infection combined with increased public awareness of the association of HPV with cervical carcinoma has led to a greater number of patients seeking counseling and treatment for condylomata (genital warts). Over 5 million new infections occur every year in the United States, and 74% are in those 15 to 24 years of age. Although there is some evidence that treatment reduces infectivity, there is no evidence supporting the concept that treatment of condylomata (the warty lesions themselves) reduces the incidence of cervical or genital neoplasia. In the majority of cases, genital HPV infection is subclinical and resolves on its own (Fig. 155-1). Treatment of subclinical asymptomatic genital HPV infection, regardless of its mechanism of detection (e.g., colposcopy, biopsy, acetic acid application, laboratory testing), is not recommended. The purpose and goal of treatment are to eliminate visible warts or symptomatic infection, to identify and resolve any associated dysplasia, and to educate the patient and any partners about the disease.

HPV is a multicentric infection. Coexisting external and internal lesions, or multiple lesions involving the entire lower genital system of both men and women, may be present. They can present as totally flat or 1- to 2-mm papular lesions, or as large, 1- to 2-cm cauliflower-like growths (see Chapter 118, Androscopy, Figs. 118-1 and 118-5). Some may be detected only with magnification (e.g., a colposcope), whereas others will be detected by a white discoloration after application of acetic acid (white epithelium). Some are flesh colored, whereas others are pigmented (see Chapter 118, Androscopy, Fig. 118-4; for a differential diagnosis, see Box 118-1). Warts may be found in and around the anus and inside the mouth. Because of the risk of neoplastic transformation, a biopsy should be obtained if the clinician is uncertain about the diagnosis, lesions fail to respond or worsen during therapy, the patient is immunocompromised, or the lesion has an atypical, suspect appearance including pigmentation, bleeding, or ulceration.

Biopsy of suspect lesions should be performed before treatment is initiated. If biopsy is performed after treatment, it is important to communicate to the pathologist the type and amount of preceding treatment.

The clinician must decide which treatment modality is best based on clinical skill, extent of disease, cost, patient preferences, and overall chance of success. The 2006 Centers for Disease Control and Prevention Treatment Guidelines point out that there is no definite evidence suggesting any of the available treatments are better than the others or ideal for all patients. Spontaneous resolution is a possibility, and therefore observation alone without specific treatment may be a reasonable alternative for some patients. Because there is no specific "cure" for HPV infection itself, the goal of treating HPV infection is the elimination of obvious visible or troublesome lesions (the disease caused by the virus). Treatment of HPV infection is analogous to the treatment of herpes virus infection. The virus will not be eliminated, but symptoms can be controlled.

Some infections may not be grossly visible, yet still cause anogenital pruritus, burning, vaginal discharge, or bleeding. Conversely, the treatment of asymptomatic intraurethral, intravaginal, or cervical condylomata (without dysplasia) exposes the patient to treatment risk without obvious benefit.

The patient may harbor HPV DNA for life; therefore, patient education is important to prevent unreasonable expectations. Treating male sexual partners with HPV infection has not appeared to change the post-treatment failure rate in women with cervical dysplasia. These findings should not deter the clinician from appropriately counseling, examining, and treating HPV-infected men (see Chapter 118, Androscopy). All methods of treating HPV have significant failure and recurrence rates. Common modalities for treatment are noted in Table 155-1; additional information is presented in Chapter 14, Cryosurgery; Chapter 30, Radiofrequency Surgery (Modern Electrosurgery); Chapter 118, Androscopy; Chapter 137, Colposcopic Examination; and Chapter 142, Human Papillomavirus DNA Typing.

The latest in the "treatment" of HPV infection is prevention. A quadrivalent vaccine (Gardasil) is available and approved by the U.S. Food and Drug Administration (FDA) for women between the ages of 9 and 26 years. It protects against HPV types 6, 11, 16, and 18; 95% to 99% of condylomata are due to an infection with HPV 6 or 11, and 75% of cervical cancers are caused by HPV 16 and 18. Theoretically, a series of three injections effectively prevents nearly all genital warts. The vaccine has no effect on treating an infection once it is present. In October 2009, the FDA approved Gardasil for use in males ages 9 to 26 for prevention of genital warts. At the same time, the FDA also approved another HPV vaccine, Cervarix (types 16 and 18), a GlaxoSmithKline product.

## INDICATIONS FOR TREATMENT OF HUMAN PAPILLOMAVIRUS INFECTION

- Visible, acuminate condylomata
- Symptomatic condylomata

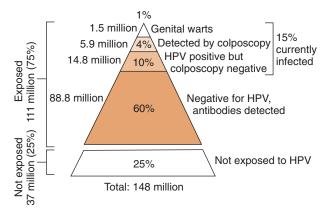

## CONTRAINDICATIONS TO TREATMENT OF HUMAN PAPILLOMAVIRUS INFECTION

## **Relative**

- Any known adverse reactions to the selected treatment modality.
- Any lesion that is possibly cancerous. (These lesions should be sampled for biopsy before treatment.)

## PREPROCEDURE PATIENT EDUCATION

Explain the procedure along with the risks and benefits to the patient. If an investigational drug is to be used, such as 5-fluorouracil ([5-FU]

**Figure 155-1** Hierarchy of clinically apparent and subclinical human papillomavirus infections: 15 to 49 years of age, United States, 2004. HPV, human papillomavirus. (From U.S. Census estimates of population as of July 1, 2004. Adapted from Koutsky L.)

Efudex; Valeant Pharmaceuticals, Aliso Viejo, Calif), review the non–FDA-approved status and why it is still being used. Counseling and education are key components in the comprehensive management of HPV-infected individuals. It is imperative that appropriate time be taken by physicians and staff to counsel patients and answer questions. Educational materials include pamphlets, printouts, videotapes, hotlines, and Internet sites (e.g., www.cdc.gov/std/hpv). Advise patients and sexual partners that although HPV infection itself has been associated with carcinoma, it is very common among sexually active adults and usually remains a benign disease that resolves on its own. Most sexually active adults will be exposed to the virus at some point in their lives. Penile penetration of the vagina is the most common mode of transmissions, but HPV can also be spread through nonpenetrative contact. Most sex partners are infected by the time the patient's diagnosis has been made, even

though they may not have any clinical evidence of infection. HPV DNA testing is currently not indicated for partners of patients with genital warts. In female patients, if not already immunized, HPV recombinant vaccine should be administered to protect against types 6, 11, 16, and 18. Prior infection with HPV is not a reason to withhold the vaccine because it may prevent infection from HPV types other than the one(s) causing the current situation. In the past, condoms were not thought to be of much benefit in providing protection, but a 2006 study by Winer and colleagues suggests a 70% decrease in risk of new infection with consistent use.

Women who develop signs of HPV infection or who are sexually active with a partner who has HPV must be advised to obtain regular Pap smears because they are at higher risk for development of dysplasia.

## **CRYOSURGERY**

See Chapter 14, Cryosurgery, and Chapter 138, Cryotherapy of the Cervix.

## **Equipment**

Cryosurgery may be carried out with a variety of methods:

- Cryogun with nitrous oxide tank and small dermal tips
- Liquid nitrogen and cotton-tipped applicators
- Liquid nitrogen pressurized sprayer (Wallach Ultrafreezer, Brymill Cry-Ac)
- Canister gases (Verruca-Freeze, Ellman Medi-Frig)

## **Techniques**

## **General Techniques for All Methods**

 No anesthetic is required for cryotherapy, although if there are large or multiple lesions, patients may prefer it (see Chapter 10, Topical Anesthesia).

TABLE 155-1 Therapies Currently Available for the Treatment of Genital Warts								
Treatment Modality	Average No. of Treatments	Success Rate <sup>†</sup>	Recurrence <6 Months	Average Length of Study Follow-up	Total Cost to Patient			
Ablative Therapy CO <sub>2</sub> laser Cryotherapy Electrocautery Infrared coagulator	1.3 1.9 1.4 1.5	89% 83% 93% 80%	8% 28% 24% 20%	13.9 mo 2.7 mo 3 mo 6 mo	\$\$ \$\$ \$\$ \$\$			
Chemical-Ablative Therapy Topical 5-fluorouracil (Eudex) 85% Trichloroacetic acid Podophyllin Podophyllotoxin (Condylox)	Patient applied 4 4.2 10.5 (patient applied)	71% 81% 65% 61%	13% 36% 39% 34%	10.9 mo 2 mo 6 mo 3.2 mo	\$\$ \$\$\$ \$\$\$ \$\$

<b>Excisional Therapy</b> Blade/scissors Radiofrequency (loop)	1.1 1	93% 90%	24% §	8.3 mo 8 mo	\$\$ \$\$			

<sup>\*</sup>Based on an estimate from the previous edition's author (Edward J. Mayeaux, Jr.) as compiled from available English-language literature. Very small studies, study results that fell 2 standard deviations beyond the means, and very poorly designed studies were excluded.

<sup>†</sup>Defined as clearance of all condylomata at end of therapy or healing from therapy.

<sup>\*</sup>Relative cost based in office visits and cost of treatment for each method. \$, low cost; \$\$, low-moderate cost; \$\$\$, high-moderate cost; \$\$\$\$, high cost.

<sup>§</sup>No data or not recorded.

2. Place the patient in the lithotomy position and examine the vulva, perineum, and rectum (or scrotum and penis). If the lesions cover a large area, it may be prudent to treat subsections at separate visits to prevent excessive post-treatment discomfort. Treatment should be directed at the acuminate warts rather than at subclinical condylomata that cannot be seen with the naked eye. Staining with dilute acetic acid may make smaller acuminate lesions more prominent.

### Nitrous Oxide

- Select the proper size of cryotip based on the size of the lesion.
   The tip should cover small lesions; larger lesions may be frozen in sections or clusters.
- 2. Moisten the lesion with water-soluble gel before positioning the probe to improve tip-to-tissue adhesion. With the cryotip at ambient temperature, place the tip on an individual lesion. Activate the cryogun to initiate the flow of gas within the probe, which begins the freezing process. Apply gentle traction on the lesion to lift the skin away from underlying tissue as soon as ice appears on the tissue (this is especially important on the penile shaft). This traction isolates the lesion from the surrounding tissue, minimizes discomfort, and ensures cold transfer. Clumped lesions may be frozen in clusters but will require longer freezing times. Clusters also require the freeze-thaw-refreeze technique to produce the necessary cryonecrosis. (The tissue is frozen until it appears solid white, then thawed until it turns pink again, and then frozen a second time.) Stop freezing as soon as the ice extends just 2 to 3 mm beyond each lesion's border. This generally takes only 15 to 30 seconds. Some practitioners prefer a second application after the initial thaw in all cases.
- 3. Explain to the patient that a tingling or burning sensation is normal, especially with thawing.

## Liquid Nitrogen (Cotton-Tipped Applicator and Spray)

- 1. Standard or large cotton-tipped applicators may be used to apply liquid nitrogen. Standard applicators (Q-Tips) work better if wisps of cotton are pulled from a cotton ball and twirled to add bulk to the end of the applicator. Pour liquid nitrogen into a Styrofoam cup. Dip the cotton-tipped applicator into the liquid nitrogen and apply immediately to the lesion. Reapply until the lesion turns white. Avoid freezing more than 2 to 3 mm beyond the border of the lesion. Thaw time should take at least 1 minute.
- 2. With the thermos-type containers (Brymill Cry-Ac and Wallach Ultrafreezer), spray a jet of liquid nitrogen on the lesions. Select an orifice large enough to have the site of the spray cover the lesion, but do not overspray. (This is a quick and economical use of liquid nitrogen.) Apply the liquid nitrogen until the lesion turns white. Avoid freezing more than 2 to 3 mm beyond the lesion. It generally takes only 5 to 10 seconds, depending on the size of the lesion. Thaw time should take at least 1 minute. A spray guard is available to protect surrounding skin. Alternatively, the physician can place an ear speculum around the lesion to limit overspray.

## Gases (Verruca-Freeze and Medi-Frig)

Verruca-Freeze and Medi-Frig work similarly to liquid nitrogen. Compressed gas in a can is sprayed into an ear speculum that should just cover the lesion. The compressed gas liquefies with spraying, and rapid evaporation results in freezing of the lesion. Use of this agent obviates the need for storing large amounts of liquid nitrogen. The speculum must be positioned so that it is perpendicular to the lesion; in this way it acts like a funnel. This position requirement may be impractical on the genitalia. Once the material is sprayed into the speculum, it is held in place until the bubbling stops. Care must be taken that the liquid does not leak out from under the speculum and freeze normal tissue. One application may suffice on small lesions. If the lesions are large, a second application may be necessary after thawing. There are also cotton-tipped applicator—

like attachments that allow this device to be used in a manner similar to liquid nitrogen.

## **Postprocedure Patient Education**

- Usually no postprocedure medication is needed. Topical anesthetic ointments may be used to minimize discomfort (e.g., lidocaine 5% ointment). Sitz baths may aid resolution when large areas are treated. Silver sulfadiazine (Silvadene) ointment or other over-the-counter antibiotic ointments (Polysporin, Bacitracin) may not only be soothing but may reduce the possibility of superficial infection. They also help keep the denuded tissue from sticking to underclothing. No dressing is required, but some patients may request a sanitary napkin.
- Lesions that are cryonecrosed progress from erythema to edema and then turn black. They may also blister. The blister may be left intact or removed. The lesions disappear within a few days, and healing should be complete in 7 to 8 days.
- The patient should be advised to report any signs of infection or excessive discomfort.
- Treated areas should be washed with mild soap and water several times each day. Postcryotherapy management is similar to that for a second-degree burn.

## **Complications**

- If the area treated at one visit is too large, extensive necrosis and pain may occur. It is prudent to treat large areas over multiple visits. Infection may occur at the treatment site if the area is not kept clean by normal hygienic measures.
- Recurrence or persistence of lesions is common.
- Cryotherapy is probably the safest therapy for treating HPV lesions during pregnancy.
- Nitrous oxide cryoguns are associated with a higher risk of perforation and fistula formation inside the vagina compared with the cotton-tipped applicator method.

## **Suppliers**

See Chapter 14, Cryosurgery.

## **CHEMICAL CAUTERY**

## **Equipment**

- Bichloracetic acid (BCA), 85% trichloroacetic acid (TCA), or 0.5% podofilox (Condylox)
- Cotton-tipped applicators or toothpicks

## **Technique**

1. For BCA, TCA, or podophyllin, identify the lesions to be treated. For small lesions, use the wooden end of the cotton-tipped applicator or a toothpick to apply the solution directly on the lesion. Avoid getting the solution on normal skin. However, the wart virus is often present 3 mm beyond the obvious lesion. Do not apply petrolatum or other ointments around the lesions, as may have been the custom in the past. Besides being time consuming, it often covers the lesion itself and protects exactly what is meant to be treated. For larger lesions, use the cotton-tipped end of the applicator to apply the solution, again being careful to avoid getting the solution on normal skin. Continue in the same manner until all the lesions are treated. With high-strength acid application, the warty tissue rapidly turns white (see Chapter 118, Androscopy, Fig. 118-7A and B). Although in the vast majority of patients this treatment method is extremely well tolerated, patients treated with acids do experience intense, burning-like pain that subsides in about 5 minutes. In 1 to 2 days

- the skin will slough. Patients may need retreatment every 1 to 3 weeks until the lesions resolve. The acids can be used in pregnancy and on mucous membranes.
- 2. Patients may apply topical 0.5% podofilox solution or gel themselves at home. Podofilox is a pure standardized compound of the active ingredient in podophyllin. Podofilox is indicated for topical treatment of external genital warts, but it is not indicated for the treatment of mucous membrane (urethra, rectum, vagina) condylomata. Podofilox is applied to the warts with a cottontipped applicator supplied with the medication. Treatment should be limited to an area less than 10 cm<sup>2</sup>, and no more than 0.5 mL of the solution should be used each day. The solution is applied in the morning and evening for 3 consecutive days; then a 4-day waiting period is observed, during which the solution is not applied. This 1-week treatment cycle may be repeated up to four times, until there is no visible wart tissue. Remember the "2-3-4-4 Rule": twice a day for 3 days, off for 4 days, used for up to 4 weeks. Later, the entire treatment can be repeated if needed. Podofilox should not be used in pregnant women, young children, and nursing mothers.

## **Complications**

- Treatment with too much solution can lead to excessive tissue damage and prolonged healing.
- Persistence and recurrence of the warts are not uncommon.
- Systemic reactions with extensive exposure to podophyllin may include nausea, vomiting, fever, confusion, coma, renal failure, ileus, and leukopenia. Local reactions include erosions, ulcerations, scarring, balanitis, and phimosis.
- Seizures and death have occurred with application of podophyllin to occluded mucous membranes.

## **Postprocedure Patient Education**

- For lesions that are cauterized chemically, the healing process is usually less than 1 week but may take longer.
- Patient education sheets are supplied by the manufacturer of podofilox.

## **INTERFERON THERAPY**

## Indication

Interferon therapy is indicated for recalcitrant condylomata unresponsive to other modalities.

## **Contraindication**

Pregnancy is the only contraindication.

## **Equipment**

- Recombinant interferon alfa-2b
- 27- to 30-gauge needle and a 1-mL syringe

## **Technique**

- The manufacturer recommends that only five warts be treated at one time, making this treatment time consuming and expensive. It is rarely used.
- 2. The standard dose is 1 million U of interferon (0.1 mL) intralesionally three times a week for 3 weeks (total of nine injections).
- 3. Use a 27- to 30-gauge needle to inject the interferon directly into the center of the wart's base (intralesional).
- Maximum response should occur within 4 to 6 weeks. If there is no clinical response after 16 weeks, a second 3-week course should be completed.

## **Complications**

- Flulike symptoms such as myalgias, fatigue, headache, chills, and fever may occur.
- May cause menstrual problems in adolescents.
- Treatment beyond 3 weeks may cause reversible leukopenia and liver enzyme elevations.

## **Postprocedure Patient Education**

• The patient may take an analgesic if flulike symptoms develop.

## **ELECTROSURGERY OR LASER THERAPY**

Treatment of warts with electrosurgery can be ablative or excisional (see later). Lesions that are small or few in number can be cauterized easily with a ball or needle electrode. Place the electrosurgical unit on coagulation (or hemostasis) with just enough power to "cook" the wart. Wipe away the debris. If viable tissue remains, touch the wart again with the electrode. Condylomata are epidermal, and there is little need to go deep. With "just enough" current there will be little scarring. An alternative approach is laser ablation, but this treatment is expensive. Its use is more commonly reserved for when there are extensive condylomata on the vulva or when the vagina or cervix also needs treatment (Fig. 155-2).

## **INFRARED COAGULATION**

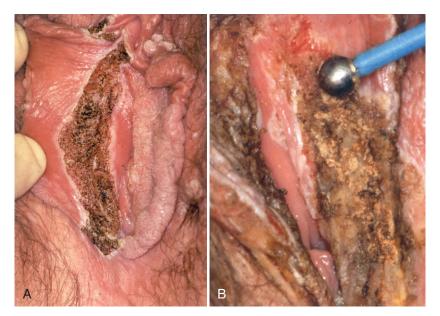

Infrared coagulation can also be used to ablate warts on the external genitals as well as mucous membranes. Its advantages are that it is quick and the depth of destruction is readily controlled by the automatic timer (see Chapter 106, Office Treatment of Hemorrhoids). Destruction occurs when infrared light travels down the light guide and concentrates on the lesion. There is no electrical current involved.

## **Technique**

- 1. Anesthetize lesions.
- 2. Set timer on 1 to 1.25 seconds for the average lesion. If the lesion is quite thick, the unit can be set up to 3 seconds. The depth of penetration will be roughly 1 mm/sec.
- 3. Apply the Teflon-coated tip inside the disposable sheath to the lesion using slight pressure.
- Pull the trigger and hold it in place until it automatically turns off. The light will not harm the eyes, although it is bright and uncomfortable if directly viewed.
- 5. Wiping the tip and allowing the tip to cool for a few seconds between applications is recommended.
- If the lesion is large, reapplication is carried out with slight overlapping.
- 7. Wipe away the ablated tissue with moistened gauze and determine if depth is adequate.
- 8. Treat the next lesion.
- 9. Postoperative treatment is the same as noted for other ablative treatments with electrocautery and acids.
- 10. Reexamine and retreat if necessary in 3 to 4 weeks. Expect slight denuding of the epithelium and mild ulceration as seen with topical acid treatments. There usually is little residual scarring.

## **SURGICAL REMOVAL**

Condylomata can be excised surgically with sharp iris scissors (see Chapter 118, Androscopy, Fig. 118-6) or a knife blade after appropriate anesthesia. However, the penile and vulvar skin is thin; it is easy to resect too deeply, which may result in scarring. Sharp disposable curettes offer a good alternative. Warty lesions also tend to be vascular and bleed easily. Although this can be controlled with

**Figure 155-2** Treatment of condyloma with laser (**A**) and ball electrocautery (**B**). (From Ferenczy A, Behelak Y, Wright TC, et al: Treating vaginal and external anogenital condylomas with electrosurgery vs CO<sub>2</sub> laser ablation. J Gynecol Surg 11:41–50, 1995.)

Monsel's solution, it is often easier to use radiofrequency (loop) excisional surgery, especially for bigger lesions (see later discussion, as well as Chapter 30, Radiofrequency Surgery [Modern Electrosurgery]). For small pedunculated growths, scissor excision may be ideal. Flatter papular lesions can usually be easily curetted with a sharp, disposable 2- to 4-mm dermal curette.

## LOOP RADIOFREQUENCY ELECTROSURGICAL EXCISION

This technique is especially useful for large condylomata, in which any type of excisional process can create excessive bleeding. Use of the radiofrequency (a type of electrosurgery) unit can readily control this excess. Using a pure cutting setting minimizes any scarring, and there is still at least a 10% coagulation current. Thus, removal is carried out quickly with minimal residual tissue destruction. Complete details of this technique are found in Chapter 30, Radiofrequency Surgery [Modern Electrosurgery].

## Equipment

- Square or round/oval loop electrodes (Usually the larger oval loops work best. Use dermatology electrodes with shorter shafts rather than the longer ones used to carry out the loop electrosurgical excision procedure [LEEP]. The shorter shafts allow better control of depth, and the operator's hand can be stabilized against surrounding tissue.)
- Electrosurgical generator
- Colposcope or 3× to 5× magnification lens (helps to keep the loop superficial, avoiding deep excisions as well as ensuring that all the lesion has been removed)
- Grounding pad or antenna
- Smoke evacuator
- 2% lidocaine with or without epinephrine (epinephrine is generally not used on the penis)
- Syringe with 30-gauge needle
- Ball electrodes (5 mm) to cauterize any bleeders
- Antibiotic ointment (over-the-counter preparations Bacitracin and Polysporin work well)
- Virus-filtering (submicron) mask and nonsterile gloves
- 4 × 4 sterile gauze pads
- Acetic acid

- Monsel's solution
- Formalin bottles
- 5% lidocaine ointment to apply after excisions completed

## **Suppliers**

See the list of companies for radiofrequency units in Chapter 30, Radiofrequency Surgery [Modern Electrosurgery], and Chapter 149, Loop Electrosurgical Excision Procedure for Treating Cervical Intraepithelial Neoplasia.

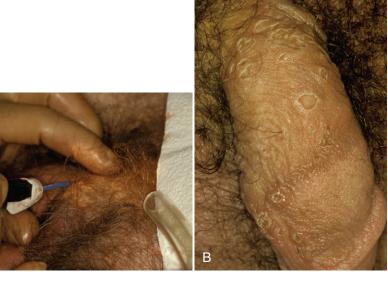

## **Preprocedure Patient Preparation**

Explain the procedure to the patient and obtain informed consent. The major risks are pain, bleeding, infection, recurrence, and scarring.

## **Technique**

See Figures 155-3 and 155-4.

- 1. Apply 5% acetic acid (or white vinegar) to the warts. Keep the tissue moist by repeated acetic acid application.
- 2. Turn on the electrosurgical generator power supply. Check the manufacturer's guidelines for proper power settings (usually around 15 to 20 W or, if using the Ellman unit, level 2).
- 3. Select the cutting (preferred) or blend mode on the electrosurgical generator.
- Place the grounding pad or antenna on the patient's thigh or buttocks.
- With a 27- to 30-gauge needle, inject 2% lidocaine under the base of the wart(s) to make a wheal that extends beyond the margin of the wart.
- Activate the smoke evacuator and place the hose close to the excisional site.
- 7. Using a method of magnification allows more precise removal and assurance that small lesions are not missed. The loop should not excise deeper than 1 mm to the dermal–epidermal junction (looks like chamois cloth). Often it is best just to "debulk" the wart on the first pass. Then make fine, superficial "feathering" strokes to remove the remaining tissue. Significant bleeding may be a sign that the excision is too deep or, paradoxically, that there is residual wart tissue. To control the depth of

**Figure 155-3** Treatment of condyloma using radiofrequency loop excision. During (**A**) and immediately after (**B**) removal. Note lack of bleeding. (Courtesy of The Medical Procedures Center, PC, Midland, Mich/John L. Pfenninger, MD.)

excision and stabilize the loop, place the fifth finger of the hand holding the electrode in the pencil wand on the patient. Should the patient jump or move, the operating hand will move too, avoiding a deep cut. Hold the pencil wand close to where the electrode inserts into the wand. Use caution because the loops cut very quickly. Be especially cautious over the penis.

- 8. After the loop electrode has been used to excise the wart, the ball electrode may be used to coagulate any bleeders or residual tissue, although this is rarely necessary.
- 9. Remove the coagulated remnants with gauze sponges soaked with acetic acid (5%).
- 10. On completion, inspect the excised area with the colposcope to ensure that the entire wart has been removed and that no coagulated remnants are left at the base of the excised lesion. Also be sure no small lesions have been missed.
- 11. Apply an antibiotic ointment and/or lidocaine ointment to the excision area and use gauze pads to cover the excision sites.
- 12. Although not mandatory, consider sending all tissue that was removed for histologic evaluation. Many lesions that appear totally benign and clinically are condylomata can be dysplastic or, albeit rarely, verrucous carcinoma.

**NOTE:** Many patients prefer this modality over chemical cautery methods because healing is often more rapid and less painful.

## **Complications**

- Hypopigmentation may rarely occur at the excision site.
- If Monsel's is used to control bleeding, there may be some residual ferrous pigmentation for several months. This gradually fades.
- Keloids may form on skin that has a tendency toward keloid formation
- Postprocedure bleeding and wound infection are extremely rare.
- According to Ferenczy (1990), the treatment failure rate at 8 months (average two treatments) is 19%.
- If the procedure is performed correctly, scarring is minimal and comparable to that with laser ablation.

## **Postprocedure Patient Education**

 Provide the patient with the sample patient education handout available online at www.expertconsult.com. Instruct the patient that some postprocedure discomfort may last for up to 2 weeks. However, initial discomfort should resolve in 24 to 48 hours and is well controlled with nonsteroidal anti-inflammatory drugs. When large areas have been treated, sitz baths may be taken two to three times a day during the initial recovery period. At a minimum, the area should be washed three to four times per day, followed by application of an antibiotic ointment. This is

Figure 155-4 Treatment of condyloma using radiofrequency loop excision. Appearance before (A) and I month after (B) removal. (Courtesy of The Medical Procedures Center, PC, Midland, Mich/John L. Pfenninger, MD.)

continued for 5 to 7 days until reepithelialization has taken place. Ice packs may also be used initially. For those patients who have perianal removals, stool softeners (docusate sodium) are important throughout the entire recovery period.

- If acute discomfort persists beyond 48 hours, instruct the patient to contact the physician. Rarely, a mixture of equal parts of 20% benzocaine (Hurricaine) ointment and topical antibiotics may be used. Lidocaine ointment 5% provides excellent relief and also keeps the tissues moist.
- Instruct the patient to return to the office in 4 to 6 weeks and to call if fever, chills, or purulent discharge develops.

## **IMIQUIMOD CREAM (ALDARA)**

Use of imiquimod (Aldara) cream is a unique approach to HPV treatment. It acts as an immune stimulator by inducing multiple subtypes of interferon-α. This causes induction of several cytokines, including tumor necrosis factor and interleukins. These in turn activate natural killer cells, T cells, polymorphonuclear neutrophil leukocytes, and macrophages, thus increasing antitumor activity. The drug has almost no systemic side effects. Use of this drug is not indicated in children younger than 12 years of age. It can be used primarily or after other treatments to reduce recurrences. In randomized, placebo-controlled trials, 37% to 54% of treated patients showed clearance after 16 weeks. Although it is an off-label indication, imiquimod has been used with excellent results to treat extensive intravaginal condylomata.

## **Indications**

It can be used on all external HPV-infected sites.

## **Contraindications**

- It is a pregnancy class C drug.
- It is not approved for use on occluded mucous membranes or on the uterine cervix. However, an off-label use for extensive intravaginal lesions is to use one packet of the cream at bedtime, once a week, for 4 to 6 weeks. It is very efficacious but may cause irritation.
- It is not recommended for use with condoms or diaphragms because of possible latex damage.

## **Technique**

The cream comes in small packets (box of 12 or 24) and is applied to the lesions three times a week for up to 16 weeks. The cream may be applied to the affected area, not strictly to the lesion itself. For best results it must be rubbed in well, not just lightly applied to the involved areas.

## **Complications**

 Side effects can include pain, pigmentary changes at application site, erythema, erosion, itching, skin flaking, and edema. Therapy may be temporarily halted if symptoms become problematic. Systemic symptoms have been reported but are extremely rare.

## **5-FLUOROURACIL**

Treatment with 5-FU should be considered only for extensive, intractable condylomata resistant to other modalities or for the treatment of vaginal intraepithelial neoplasia (VAIN). The FDA has not approved labeling of 5-FU for treatment of these diseases, and the patient should be advised that this is technically an investigational use. Because of the reported teratogenic potential, 5-FU should be used with extreme caution—if at all—in nonsterile women of reproductive age. If used, a signed consent form is advised

indicating the patient will not become pregnant. Although commonly used historically, 5-FU use has fallen into disfavor for HPV treatment because of complications of vaginal scarring and the development of other, more acceptable methods. It is still one of the easiest-to-use and most effective treatments for male urethral/meatal lesions.

## **Indications**

- Extensive vulvar, perianal, penile, or vaginal condylomata
- VAIN
- Vulvar intraepithelial neoplasia
- Urethral meatus lesions
- Bowenoid carcinoma in situ of the penis (erythroplasia of Queyrat)

**CAUTION:** Patients with blond or red hair, or with very light complexions, may be more sensitive to 5-FU. Also use cautiously in patients with known skin sensitivities such as atopic dermatitis. Mucosal areas are much more sensitive than keratinized skin.

## **Contraindications**

- Pregnancy
- Lack of birth control method (relative contraindication)
- Lack of informed consent with regard to absence of FDA approval

## **Equipment**

- 5% 5-FU (Efudex, Fluoroplex) cream
- Vaginal applicator marked with dosage lines

## **Preprocedure Patient Preparation**

- Obtain informed consent before initiating treatment.
- Advise the patient of alternative methods of treatment. Frequently when 5-FU is being considered, laser ablation or LEEP therapy is also an option.
- The patient should know that the inflammatory response is delayed by 3 to 4 days. The patient may believe the medication is not working and so apply it more frequently, leading to complications.
- Use of 5-FU should be limited to clinicians experienced with managing side effects, which are similar to those experienced when treating the face for actinic changes (e.g., chemical burns). See the sample patient education form online at www. expertconsult.com.

## **Technique**

## For the Vagina

- 1. Instruct the patient to use 1.5 g of 5-FU per week for 10 weeks. A standard Ortho vaginal applicator will hold 10 mL of cream (5 g of 5-FU). Patients should then use only one third of an applicator of cream for each treatment. The 5-FU should be inserted intravaginally or applied directly to any external lesions at bedtime (e.g., for perianal lesions).
- 2. Instruct the patient to apply zinc oxide to the vulva (where treatment is not necessary) to protect it in the event that intravaginal, perineal, or perianal 5-FU should leak out or come into contact with the vulva. This is not necessary if external condylomata exist in this area.
- 3. The patient may insert a small tampon into the vagina to keep the 5-FU within the introitus.
- 4. If there is no inflammatory response after 3 weeks, the patient may increase the frequency of application to every 5 days.

### For the Urethral Meatus

Use a cotton-tipped applicator and apply a small amount of 5-FU cream into the meatus for a distance of 5 to 6 mm. Apply after voiding at bedtime and again after voiding and showering in the morning. Repeat for 7 days. Lesions will generally resolve. If not, repeat for another 7 days. Allow any inflammation to resolve before reapplication.

## For the Penis (Carcinoma in Situ, Erythroplasia of Queyrat)

This lesion usually occurs under the foreskin. Because of occlusion, the effects are magnified. Although quite efficacious, the treatment can be quite painful, especially if the medication is overused. Also, these lesions generally occur in older men, so compliance can be difficult. Cream will often drip out on the scrotum, so it must be protected. A small amount of cream is applied once a week to the affected area for 6 weeks. If there is little reaction after the first week, the schedule can be increased to every 5 days for two periods. If there is still minimal response, the cream can be tried every 3 to 4 days, but must be monitored closely. Treatment for 6 weeks usually resolves the dysplasia, but longer treatment may be needed. Recheck 6 weeks after completing treatment to be sure the abnormality has resolved. Small residual spots may be treated with excision or electrocautery, or even more 5-FU.

## **Complications**

- Pain.
- Bleeding.
- Persistence of disease.
- Persistent vaginal ulcers may develop in patients who are extremely sensitive to 5-FU or in patients who overuse the medication. For some patients, the vaginal ulcers may fail to heal with time, and the patient may have persistent vaginal discharge and bleeding (rare). Patients who fail to heal may require surgical excision of the ulcer and primary closure of the defect.
- Vaginal stenosis (rare).
- If 5-FU is to be used after cryotherapy of the cervix, wait at least 4 weeks before initiating 5-FU therapy to avoid cervical stenosis.
- Inflammation of the scrotum, if not properly protected, when treating Bowen's disease (squamous cell carcinoma in situ).
- Foreskin adhesions.

## **Postprocedure Patient Education**

Instruct the patient to contact the physician if severe inflammation or any hypersensitivity reaction occurs. Intravaginal estrogens or steroid creams may be used to decrease the inflammatory reaction. See the sample patient education handout online at www.expertconsult.com.

## **SINECATECHINS**

Sinecatechins, a green tea extract, is approved by the FDA for the treatment of genital and perianal warts. It is a 15% ointment, produced by Bradley Pharmaceuticals (Fairfield Township, NJ), and marketed as Veregen. It is approved for use in immunocompetent patients 18 years of age or older. The recommended initial dose of the Veregen is a 0.5-cm strand applied in a thin layer over all external and perianal warts, three times a day.

In clinical trials patients applied 10% or 15% ointment three times daily for a maximum of 16 weeks or until complete resolution of the warts occurred. Complete clearance of warts was seen in 56.3% and 57.2% of patients, respectively. Partial clearance rates of at least 50% were reported for 74% and 78.4% of patients.

## GUIDELINES FOR TREATING PERIANAL AND INTRA-ANAL LESIONS

Treatment of perianal and intra-anal lesions is similar to treatment for vaginal condylomata. Additional guidelines are as follows:

- Podofilox and imiquimod should not be used on mucous membranes (i.e., inside the anus). TCA, excisional therapy, electrocautery, and infrared coagulation may be used intraanally.
- Anoscopy should be performed on all patients with perianal lesions to rule out more proximal lesions. This is often done after resolution of the external lesions to avoid possible trauma and potential spread of the virus proximally.
- The risk of rectal carcinoma is increased 50 times in receptive homosexual men, and HPV appears to be involved in the process. Some suggest Pap smears of the dentate line of the anus to detect early dysplastic lesions just as with the cervix, followed by staining and biopsy (see Chapter 99, High-Resolution Anoscopy).

## GUIDELINES FOR TREATING CONDYLOMATA IN PREGNANCY

Condylomata may grow rapidly and multiply quickly during the second-trimester immune suppression. After delivery, they may, and often do, resolve spontaneously. Women who have warts in the perineum with subsequent tears or episiotomies have a higher risk of wound dehiscence. Most physicians recommend treatment of perineal condylomata during the third trimester. Safe modalities include cryotherapy, 85% TCA, electrocautery, laser therapy, infrared coagulation, and radiofrequency (loop) or sharp tissue scissor excision. Although cryotherapy may be used, there is often more swelling and discomfort.

It appears that HPV is in the amniotic fluid of infected mothers, so there is no indication for cesarean section unless the lesions are so large that they inhibit normal delivery.

## OTHER METHODS FOR TREATING CONDYLOMATA ACUMINATA

Although Candida antigen injection is used for verrucae, there have been no published reports of its use in treating condylomata. There is theoretically no contraindication to its use, and it has been tried to some degree of success (editor's experience).

## GENERAL CONSIDERATIONS FOR ALL METHODS

See Box 155-1 for a summary of treatment options for various locations. See Figure 155-5 for an algorithm on treatment protocol selection.

- HPV is associated with cervical cancer, and women must be followed closely with Pap smears, HPV DNA typing, or colposcopy.
- The patient and partner must not smoke. Even passive smokers have been found to have lower folate levels—a known risk for HPV. Reducing smoking leads to a reduction in cervical dysplasia, whereas continuing to smoke encourages progression.
- The patient should consume a diet with at least five helpings of fruits and vegetables daily.
- Patients must be informed that they can spread the disease at any time and that monogamy is most prudent.

## Box 155-1. Preferred Methods of Treatment for Condylomata in Various Locations and during Pregnancy\*

## External Genital and Perianal

Cryotherapy

Electrocautery

Electrofrequency/radiofrequency excision

Imiquimod (Aldara)

Laser

Podofilox (Condylox)

Sinecatechins (Veregen)

85% TCA

## Cervical

Must rule out dysplasia before treatment (perform colposcopy), then the following:

Cryotherapy

Electrocautery

Excision with radiofrequency or multiple biopsies

85% TCA

## Vaginal

Cryotherapy

Electrocautery

5-FU (extensive disease)—not FDA approved Imiquimod (Aldara)—not FDA approved

Laser

85% TCA

## **Urethral Meatus**

Cryotherapy

Electrocautery

Excision

5-FU

85% TCA

## Penis or Bowen's Disease

Electrocautery

5-FU

Frank excision of lesion

## Intra-anal

FDA, Food and Drug Administration; 5-FU, 5-fluorouracil; TCA, trichloroacetic acid.

 Condoms are not needed with current partners if there has been unprotected intercourse because they already have the virus; theoretically, once infected, the patient will always harbor the virus. Condoms may protect against transmission with new partners and against other sexually transmitted infections.

**Figure 155-5** Algorithm for treatment protocol selection for condyloma. TCA, trichloroacetic acid. (From Ferenczy A: External anogenital warts: Old and new therapies. | SOGC December: 1305–1313, 1999.)

## **CPT/BILLING CODES**

11900 Injection, intralesional; up to and including seven lesions (interferon)

11901 Injection intralesional; more than seven lesions

For destruction codes, if it takes less than 15 minutes, use "simple" codes. If treatment takes longer than 15 minutes, requires use of the colposcope and an extensive examination, or is particularly complicated because of the size or extent of the condylomata, use the "extensive" codes.

46900	Destruction of lesion(s); anus (e.g., condyloma), simple;
	chemical
46910	Destruction of lesion(s); anus electrodesiccation, simple
46916	Destruction of lesion(s); anus cryosurgery, simple
46917	Destruction of lesion(s); anus laser surgery, simple
46922	Destruction of lesion(s); anus surgical excision, simple
46924	Destruction of lesion(s); anus, extensive; any method
54050	Destruction of lesion(s); penis (e.g., condyloma), simple;
	chemical
54055	Destruction of lesion(s); penis electrodesiccation, simple
54056	Destruction of lesion(s); penis cryosurgery, simple
54057	Destruction of lesion(s); penis laser surgery, simple

54060 Destruction of lesion(s); penis surgical excision, simple

- 54065 Destruction of lesion(s); penis, extensive, any method
- 54100 Biopsy, cutaneous, penis
- 56501 Destruction of lesion(s); vulva, simple; any method
- 56515 Destruction of lesion(s); vulva, extensive, any method
- 56605 Biopsy, vulva introitus
- 57061 Destruction of lesion(s); vagina, simple; any method
- 57065 Destruction of lesion(s); vagina, extensive; any method
- 57100 Biopsy, vagina

## **ICD-9-CM DIAGNOSTIC CODES**

078.10 Viral warts, unspecified

078.11 Condyloma acuminatum

## **ACKNOWLEDGMENT**

The editors wish to recognize the many contributions by Edward J. Mayeaux, Jr., MD, to this chapter in a previous edition of this text.

## **ENDOMETRIAL ABLATION**

Thomas A. Kintanar

For over a century, physicians have attempted a variety of methods to control abnormal uterine bleeding as an alternative to hysterectomy. It is estimated that nearly 50% of women will have significant, heavy menstrual bleeding during their lifetime, particularly during the fifth and sixth decades of life. In the late 1880s there was a report of a physician placing a uterine sound into the endometrial cavity of patients and attaching the sound to a series of batteries. It was noted that women who did not have uterine fibroids had significant improvement in their heavy bleeding. However, because of the lack of suitable equipment and delivery systems, interest in endometrial ablation for the treatment of abnormal bleeding was essentially nonexistent. The technique of dilation and curettage (D&C) was introduced and became the gold standard for the treatment of abnormal bleeding, even though this procedure continues to be ineffective in controlling abnormal uterine bleeding. More recently, different methods of hormone manipulation have been used with limited

Modern methods of achieving endometrial coagulation by heat had their beginning when Goldrath successfully used the neodymium-doped yttrium-aluminum garnet (Nd:YAG) laser in the early 1980s. His technique was quickly followed by other methods in which a urologic resectoscope was used to remove the endometrial lining. Resection was soon followed by rollerball endometrial ablation, in which the lining is not removed, but is destroyed by cauterization. For the past decade, the Nd:YAG laser, uterine resection, and rollerball ablation have been the primary methods used to control abnormal bleeding when hysterectomy was not desired and hormones were ineffective.

Endometrial ablation is safe, effective, efficient, and readily learned. It allows patients to address problematic vaginal bleeding from the endometrium while allowing them to keep their uterus. Methodologies that use hysteroscopy for visualization of the uterus are considered invasive. The newer techniques that do not require the use of hysteroscopy are termed minimally invasive nonhysteroscopic methods for endometrial ablation. This chapter covers the more contemporary approaches to endometrial ablation with a brief historical discussion of the classic techniques of rollerball, hysteroscopic methods of resection, and laser. At the end of the discussion, a table highlighting the U.S. Food and Drug Administration (FDA) comparative data on the five second-generation approaches is provided (Table 156-1). These data reflect the FDA Manufacturer and User Facility Device Experience (MAUDE) database review.

## **ADVANTAGES**

- Minimal anesthesia (cryoablation)
- Short operating time
- Performed in outpatient facility (rollerball and thermal balloon ablation) or office (cryoablation)

- Few complications
- Rapid postoperative recovery and return to normal activity
- Highly effective in controlling bleeding (95% success rate)
- Highly effective in controlling or eliminating associated symptoms (e.g., premenstrual syndrome, dysmenorrhea, moodiness)
- Easily mastered (cryoablation)

## **INDICATIONS**

The ideal candidate for endometrial ablation meets all of the following criteria. However, there are differences in indications and contraindications depending on which technique is used.

- Menorrhagia or heavy menstrual bleeding (defined as blood loss >80 mL/cycle; bleeding for longer than 8 days; blood loss or symptoms that interfere with normal activities; or blood loss sufficient to cause anemia)
- Pharmaceutical treatment contraindicated, failed, refused, or created adverse effects
- Desire to avoid hysterectomy, especially in those with significant medical problems and surgical risks

## **PREREQUISITE CONDITIONS**

- Absence of any precancerous or cancerous lesions of the endometrium or cervix; normal Papanicolaou (Pap) smear and negative endometrial biopsy or hysteroscopy.
- Uterine size less than 12 weeks of gestation and uterine cavity less than 12 cm in length (with the cryoablation technique, large uterine size does not preclude performing the procedure).
- Other potential causes of excessive menstrual bleeding that could be treated medically or by other alternative forms of surgery have been excluded.
- No underlying uterine lesions requiring surgery.
- Childbearing has been completed.
- No active pelvic infection.

## **CONTRAINDICATIONS**

## **Absolute**

- Current or planned pregnancy
- Presence of cervical or endometrial cancer or precancer
- Myomas in uterus larger than 4 cm
- Previous uterine surgeries such as myomectomy, classic cesarean section (excluding low transverse cesarean section), or any uterine surgery that would render the myometrium thin (e.g., deep myomectomy)
- Clotting or bleeding disorders
- Adnexal masses

TABLE 156-1	Comparative Data from 2001	U.S. Food	and Drug	Administration	Trial of Five	Second-Generation
Endometrial	Ablation Devices					

Device Characteristic	Balloon	Cryotherapy	Radiofrequency	Hydrothermal	Microwave
Operating principle	Balloon filled with fluid (5% dextrose in water) at 87° C	Probe with transfer media creates ice ball at -100° C to -120° C	Bipolar, radiofrequency ablation at 180 W	Hydrothermal circulation of saline at 90° C	Controlled microwave tissue ablation delivered through hand-held applicator
Average treatment time	8 min	10-18 min	90 sec	10 min	3.5 min
Average procedure time	20 min	30 min	4.2 min	30 min	Not reported (~11 min including hysteroscopy)
Direct visualization	None; done before procedure	Ultrasonography	None required; visualization before and after procedure	Hysteroscopy	Done before procedure; continuous temperature readings taken during procedure
Pretreatment	3-min suction curettage	Leuprolide acetate	None required	In FDA trial, patients received a 7.5-mg dose of leuprolide acetate administered 3 wk before ablation; other trials used 3.75-mg dosages. Treatment occurred on days 19–27 after injection.	Leuprolide acetate (3.75 mg)
Safety features	Pressure shut-off at >210 mm Hg or <45 mm Hg; terminates if temperature >95° C or <75° C	Ultrasonographic visualization provides guidance for ice ball progression	Tests for perforations; terminates procedure at proper tissue impedance	Automatic shut-off at fluid loss of 10 mL or increase of 20 mL	Tests for abnormal temperature rise; terminates procedure
Patients enrolled in FDA trial: selected inclusion criteria	Uterine sound measurement of 4–10 cm	Uterine sound measurement of <10 cm Uterine volumetric measurement <300 mL	Uterine sound measurement of 6–10 cm Polyps <2 cm Submucous fibroids that did not distort the uterine cavity	Endometrial cavity measuring <10.5 cm	Uterine sound measurement of 6–14 cm Polyps or submucous fibroids allowing distortions up to 3 cm
Patients enrolled in FDA trial: selected exclusion criteria	Cavity >10 cm Submucous fibroids Polyps Septate uterus Previous endometrial ablation procedure Classical cesarean section	Intramural myomas >2- cm diameter Intrauterine polyps Pedunculated fibroids Septate uterus	Abnormal/obstructed uterine cavity as confirmed by hysteroscopy, saline-infused sonogram, or hysterosalpingogram Specifically, septate or bicornuate uterus, pedunculated submucosal leiomyomata, or polyps (>2 cm) likely to cause menorrhagia Previous uterine surgery interrupting integrity of uterine wall	Intramural fibroids >4 cm on sonography contributing to menorrhagia Uterine anatomic anomaly Previous endometrial ablation procedure Classical cesarean section	Previous uterine surgery or other condition that interrupts integrity of myometrial wall

Data from Sanfilippo JS (ed): Options in Endometrial Ablation. Supplement to OBG Management, December 2005. Available at www.obgmanagement.com/mededlibr/PDFs/I 205Suppl EA.pdf.

## Relative

- Uterine size greater than 12 cm (this may vary depending on the procedural approach of the surgeon).
- Total cervical stenosis.
- Previous endometrial ablation.
- Unusual anatomic variation that may preclude adequate ablation, such as congenital uterine abnormalities. If there is a septate or bicornuate uterus, both cavities must be ablated separately; in the case of hydrothermablation, this may constitute a relative contraindication. Clinical consideration and procedural approach must be taken into account before proceeding with the ablation procedure of choice.

## **EQUIPMENT AND SUPPLIES**

Because there are different systems that use supplies specific to the particular procedure, the following equipment/supply list provides the most often required supplies to perform the majority of the procedures. A list of equipment/supplies germane to each procedure is listed with each particular section.

- For hysteroscopy-based ablation, a rigid (0-, 12-, or 30-degree viewing angle) hysteroscopic resectoscope (Fig. 156-1)
- Uterine sound
- Hegar cervical dilators
- Tenaculum

Figure 156-1 Full resectoscope kit. A, Hysteroscope. B, Operating sheath. C, Continuous-flow sheath.

- Vaginal bivalve speculum
- Antiseptic solution
- Lidocaine 1% with 10-mL syringe and 4-inch needle extender, 25-gauge needles (optional)
- Light source
- Uterine distention system (CO<sub>2</sub> or fluid) for hysteroscopy-based systems (see Chapter 140, Hysteroscopy)
- Energy source and ablative attachments (laser or cautery, thermal balloon, and cryosurgical ablation techniques do not require these components)
- Video camera and display monitor for hysteroscopy-based systems

## **PRECAUTIONS**

Endometrial ablation does not exclude the possible future development of endometrial cancer or pregnancy. Although the risks of these are low, patients should be made aware of this before undergoing the procedure. If a patient is on estrogen therapy after endometrial ablation, progestin supplementation is still necessary to prevent the development of atypical endometrium.

If the patient is still of childbearing age and pregnancy is a distinct although distant possibility, contraceptive measures should be taken to ensure pregnancy is prevented.

## PREPROCEDURE PATIENT EDUCATION AND FORMS

Endometrial ablation is such a life-altering procedure that it is the surgeon's obligation to provide the patient with all of the information needed to understand all of the possible outcomes (see the example patient education form online at www.expertconsult.com). Some key elements of discussion are to emphasize that ablation *may* induce sterility but does not guarantee that pregnancy will not occur. Another element is that sexual desire should not be affected by the procedure. Because the endometrium is the only focus of treatment, and not the ovaries, hormonal cycles will continue if the patient is premenopausal.

## PREPROCEDURE PATIENT PREPARATION

- In most instances, the patient will have already had endometrial sampling performed in the investigation of her abnormal bleeding. If this has not been done, endometrial sampling should be performed in advance of the procedure to verify the absence of malignant or premalignant lesions.
- Screening for cervical cancer (Pap smear) should also be up to date.

- Pregnancy should be excluded at the time of the procedure.
- Preoperative ultrasonography is helpful to ascertain the endometrial thickness and assess the uterine anatomy. The ideal thickness of the endometrium for ablation is less than 3 to 4 mm. There are several ways to reach this goal:
- Physiologically, the late menstrual or early proliferative phase of the cycle will provide the ideal setting for proceeding without the use of pharmacologic agents.
- Another simple approach would be to perform the ablation immediately after curettage.
- To produce an atrophic, thin endometrium before the surgery, pharmacologic agents may be used. This will allow for more efficient ablation and lessen bleeding to decrease postoperative anemia. Agents available are either antiestrogenics such as danazol (600 to 800 mg daily for 3 to 12 weeks) or gonadotropin-releasing hormone (GnRH) agonists such as leuprolide acetate (two 3.75-mg intramuscular injections administered 3 to 4 weeks before surgery) or goserelin (3.6 mg injected subcutaneously 3 to 4 weeks before surgery). Pharmacologic preparation is not required with use of the NovaSure.
- Laminaria tent placement the day before the procedure will enhance cervical dilation. However, care must be taken to limit cervical dilation owing to concerns regarding the seal that the cervix can provide during the procedure, as in the case of the hydrothermablation procedure or the NovaSure.
- Antibiotic prophylaxis is unnecessary in most cases.

Preoperative preparation in this manner can decrease surgical time, lessen fluid absorption, and improve safety and surgical outcome for the patient.

Appropriate anesthesia for these procedures varies with the procedure, patient, physician, and clinical setting. Paracervical block, sedation, regional anesthesia, general anesthesia, or a combination of these should be considered.

## **PROCEDURE**

The following descriptions summarize the procedures in the most succinct manner. However, the focus is on the more contemporary techniques, with as much detail as possible. Inclusion of the rollerball and laser ablation is of more historical rather than practical value given the advent of the more contemporary ablative techniques. Some of the new-generation techniques for endometrial ablation do not require the use of the hysteroscope and are termed minimally invasive nonhysteroscopic methods for endometrial ablation. Discussion of long-term success rates regarding issues such as amenorrhea, patient satisfaction, and the eventual need for hysterectomy is well covered in the references provided in the Bibliography.

## **Anesthesia**

The anesthesia provided for the rollerball and laser procedures is usually general anesthesia, but with the new procedural approaches, paracervical block along with oral analgesics may be all that is required to effect adequate clinical comfort. The paracervical block is used in several of the new techniques (see Chapter 173, Paracervical Block).

## Technique of Hysteroscopic Endometrial Ablation with Rollerball

A rigid (0-, 12-, or 30-degree viewing angle) hysteroscopic resectoscope (see Fig. 156-1) is necessary for this procedure.

The objective of this procedure is to ablate the basal layer of the endometrium as well as the first few millimeters of the myometrium in order to ensure endometrial destruction. The first pass of the rollerball ablates to a depth of approximately 3 mm, exposing the

base of the endometrial glands. The second pass ablates 2 to 3 mm of myometrium.

For the surgeon to adequately visualize the entire uterine cavity, it must be distended with liquid. Operative hysteroscopy usually uses a low-viscosity medium that continuously flows into and out of the uterus, clearing out surgical debris and blood and improving the surgeon's field of view. An inflow pressure of 80 to 110 mm Hg ensures optimal distention and continuous irrigation. An automated irrigation delivery system may be used, or a bag of distending medium is hung 1 m above the patient and produces distention through gravity. Distention media used during endometrial ablation include hypotonic agents such as glycine (1.5%), sorbitol (3%), or mannitol; isotonic agents such as normal saline; or the high-viscosity agent, dextran 70 (a viscous solution of 32% dextrose). Infused and collected fluid volumes are measured every 5 minutes, and consideration should be given to terminating the procedure if the fluid accumulation exceeds 1 to 1.5 L.

### Procedure

Under sterile conditions, perform a standard bimanual pelvic examination to ascertain uterine position.

- 1. Insert bivalve speculum to expose the the cervix. Another alternative would be to place a weighted speculum in the posterior vaginal cavity and use an anterior retractor to expose the cervix, thus maximizing exposure of the cervix.
- 2. Grasp anterior lip of cervix with fine-tooth tenaculum.
- 3. Gently sound the uterus with a uterine sound. The tenaculum can be used to provide uterine stability.
- 4. Use Hegar dilators to gradually dilate the cervix (usually 8 to 12 mm to provide enough width to advance the resectoscope component of the hysteroscope). Also be careful to not overdilate the cervix because this may induce leakage of distention media, thus limiting the view. If this does occur, a fine-tooth tenaculum may be used to approximate the loose cervical edges.
- 5. Assemble the resectoscope, making sure the advance and retraction capability is in order. (There is a paradoxical mechanism in all resectoscopes. Pulling the trigger advances the rollerball and gently relaxing pressure retracts the rollerball. The pushing and pulling of the trigger creates the extension/retraction of the rollerball, which effects the rowlike destruction of the endometrium. The rollerball is a spherical or barrel-shaped electrode that rolls over the endometrium at a speed of 10 to 15 mm/sec [Fig. 156-2]).
- 6. Insert the resectoscope by gentle advancement under direct visualization, following the lumen, with the irrigating fluid flowing (very similar to advancing a rigid sigmoidoscope).
- Identify landmarks (bilateral tubal ostia and fundal area; see Chapter 140, Hysteroscopy).
- 8. Gently advance the rollerball by pulling the trigger until it approximates the proximal segment of the internal os. About 1.5 cm below (distal to) the internal os, set the end-point line of demarcation for ablation. Cauterize the entire circumference of this area by placing the rollerball directly on the segment by gently maneuvering the resectoscope. This creates a ringlike area of destruction that marks the eventual end point for the rollerball retraction.
- 9. Activate the cautery source by the foot pedal, set to a coagulating power of 50 to 80 W. There are differing viewpoints on the average power. Some operators use up to 200 W. There are also recommendations to start at 60 W to destroy the endometrial tissue for the first layer of endometrial destruction, followed by an increase to 80 to 100 W for subsequent passes. Visualize the entire distended uterine fundus and then start ablating the fundus by contacting the rollerball with the fundal tissue in a right-to-left manner. When performing ablation on the fundus, the rollerball is extended to near its maximum. The rollerball "paints" the fundus in a right-to-left manner in rows until the

Figure 156-2 Examples of rollerball ablation probes.

fundal area is entirely ablated. The ostia are handled in a similar fashion. However, because the ostial area is spherical, the rollerball must be rotated within the resectoscope to contact the tissue, consistent with the anatomy being ablated. After the line of demarcation has been established at the internal os, the corpus is ablated with the rollerball fully extended, starting at the fundus at around 6 o'clock. Advance the rollerball to the fundus to ablate the entire fundal and periostial area. Gently advance the rollerball to full or nearly full extension to the fundus, then retract in a linear fashion while activating the energy source to destroy the endometrium. A count of "one thousand one, one thousand two, one thousand three" should be used to effect a subjective but fairly accurate time for contact of the rollerball with the tissue during the ablation process. Continue this in a row-by-row fashion, destroying 360 degrees around the entire endometrial cavity two to three times, ending once again at 6 o'clock position.

- 10. On completion of the procedure, check the fluid balance to confirm minimal risk of postoperative fluid overload.
- 11. Remove all instruments and transport the patient to recovery.

## **Common Errors**

- Equipment malfunction or poor assemblage of the equipment
- Poor endometrial preparation resulting in less than optimal longterm outcomes
- Fluid leakage resulting in inaccurate fluid balance estimation

## Complications

The media used to distend the uterine cavity during hysteroscopy can cause fluid overload, allergic reactions, and other toxic reactions. Fluid overload is associated with prolonged operating times and the use of high distending pressures.

• Absorption of excess amounts of hypotonic distending solution results in increased central venous pressure and hyponatremia that, if untreated, lead to pulmonary edema, hypotension, cerebral edema, and potentially fatal cardiovascular collapse. To avoid these complications, intraoperative fluid use must be strictly monitored during the procedure and the patient observed for signs and symptoms of fluid overload. Most physicians will stop a hysteroscopic procedure at a 1- to 1.5-L fluid deficit when using glycine, sorbitol, or mannitol to avoid hyponatremic hypovolemia. A lower threshold may be required for older patients or those with preexisting cardiovascular problems. Dextran 70 has been associated with fluid overload, pulmonary edema, intravascular coagulopathy, renal insufficiency or failure, rhabdomyolysis, and anaphylactoid reactions. Glycine can result in hyperammonemic encephalopathy and transient blurred vision and blindness.

- Mechanical complications include air embolism, cervical laceration, perforation of the uterus, and severe hemorrhage.
- Thermal damage to the bowel, although rare, may occur with rollerball or laser ablation.
- Endometrial cancer may persist if occult presence is not diagnosed before the ablation, making diagnosis afterward very difficult.
- Pregnancy, although rare, is possible. With a very thin posttreatment endometrium, there is a higher risk of ectopic pregnancy as well as poorly sustained placenta and embryonic implantation.
- Infection.

## Postprocedure Management

Consideration should be given to the use of postoperative antiemetics and pain medication. Options for pain control include nonsteroidal anti-inflammatory drugs (NSAIDs), opiates, and acetaminophen. The patient should be instructed to have a return appointment at the surgeon's office within 1 to 2 weeks and be apprised of possible postoperative complications such as prolonged bleeding, vaginal discharge, infection, and abdominal discomfort.

## **Endometrial Laser Ablation**

A resective hysteroscope with Nd:YAG laser attachment is necessary for this procedure.

Endometrial laser ablation is performed as an inpatient or outpatient procedure under general or regional anesthesia. A distention medium, usually normal saline, is delivered into the uterus by peristaltic pump, sphygmomanometer, or gravity, and uterine pressure is maintained between 80 and 100 mm Hg. The amount of medium is measured so that the development of fluid overload can be monitored. The Nd:YAG 600- $\mu$ m fiber can produce 17,000 W/cm² at 60-W power when maximally focused. Characteristic front-scatter, coagulation, and bubbling occur during the process. A 1200-mm microfiber at same power will produce 4200 W/cm².

## Procedure

- 1. Repeat steps 1 to 7 from the hysteroscopic rollerball ablation section, earlier.
- 2. The rigid hysteroscope is placed, and the endometrium is visualized. The laser attachment is placed through the operating channel of the hysteroscope and activated at a power level of approximately 60 to 80 W delivered by a 600-µm bare quartz fiber.
- 3. There are two techniques used for endometrial laser ablation, the touch or drag technique and the nontouch or blanching technique. During the *touch technique*, the laser tip is lightly applied to the endometrial surface and gently swept across the uterine cavity. For the *nontouch technique*, the laser tip is brought within 1 to 5 mm of the endometrial surface but does not touch it. Compared with the touch technique, this technique reduces the potential for fluid absorption because the blood and lymphatic vessels are coagulated as opposed to being cut open. Some physicians use a combination of the two techniques. Ablation begins at the cornual and fundal areas with the delivery of short, 5- to 10-second bursts of laser energy. The anterior wall is ablated to the level of the cervical os, followed by ablation of the lateral and posterior walls.
- 4. The Nd:YAG laser coagulates and denatures the endometrium to a depth of approximately 4 to 6 mm. As coagulation proceeds,

tissue damage is minimized because the laser energy absorbed decreases and the amount reflected increases. Fluid balance is calculated every 5 minutes and intravenous (IV) furosemide is given if the fluid absorption exceeds 1500 mL. Endometrial laser ablation takes approximately 30 to 180 minutes. If the procedure is successful, postablation histologic study months later will reveal a single layer of simple cuboidal epithelium devoid of endometrial glands.

5. Remove all of the instruments and transport patient to recovery.

## **Common Errors**

Potential errors are the same as for the rollerball technique.

## **Complications**

Complications are the same as for the rollerball technique.

## Postprocedure Management

Postprocedure management is the same as for the rollerball technique.

## Thermal Balloon Ablation of the Endometrium

A 30-mL syringe, ThermaChoice III disposable kit, and generator are necessary for this procedure.

The ThermaChoice (Gynecare, Inc., Menlo Park, Calif) kit consists of a disposable balloon catheter with an outside diameter of 5 mm and a plastic catheter that connects the balloon catheter to the fluid line and the umbilical cable. The controller unit displays the temperature, pressure, and clock (time) as well as providing the base of connections for power and the umbilical cord to the catheter (Fig. 156-3). An excellent educational module is available that covers all aspects of the procedure in detail (available at www.interact3d.com/modules/).

## Procedure

This procedure does not require the use of a hysteroscope as in the previously described techniques. This approach was the first of the newer minimally invasive nonhysteroscopic methods for endometrial ablation.

- 1. Priming the catheter with 15 mL of  $D_5W$  is the first step in the procedure. Fill the catheter with the balloon tip facing downward, keeping the catheter vertical until priming is complete and the catheter is full. Once the priming is finished, attach the syringe with  $D_5W$  to the catheter and inflate the balloon with 10 mL of  $D_5W$  to ensure its patency. Withdraw air bubbles and  $D_5W$  through the syringe until a negative pressure of 150 to 200 mm Hg is attained as noted on the monitor.
- 2. Repeat steps 1 to 3 from the hysteroscopic rollerball ablation section. The ThermaChoice is approved in the United States for ablation in uteri sounding from 4 to 10 cm, although it may be used in uteri sounding up to 12 cm.
- 3. A paracervical block is administered along with preoperative provision of long-acting NSAIDs to minimize patient discomfort. This procedure is routinely performed in the office setting, but it may also be performed in an operating suite. The choice of anesthesia will depend on patient—physician interaction.
- 4. Sound the uterus, then insert the balloon catheter into the cervix. The outer sheath measures 5 mm, which makes insertion relatively easy and usually obviates the need for cervical dilation.
- 5. The catheter is filled with a small volume of sterile  $D_5W$  (usually 15 to 30 mL) to conform to the shape of the uterus and until a balloon pressure of 160 to 180 mm Hg is identified on the ThermaChoice generator. Titration of the fluid volume will achieve the proper therapeutic pressures. Pressing the valve control button on the catheter adds or removes fluid to titrate the pressure. As the balloon enlarges, the endometrial cavity will relax

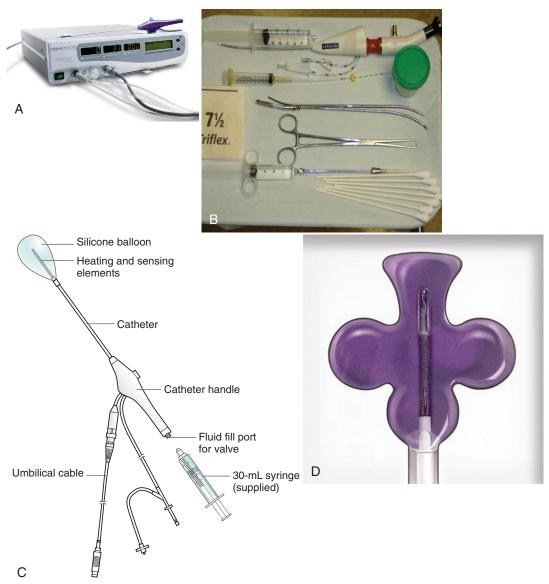

Figure 156-3 Gynecare ThermaChoice III Uterine Balloon Therapy System for performing thermal balloon ablation, with element tray and demonstration of balloon insufflation in a model uterine cavity. A, ThermaChoice III module. B, ThermaChoice surgical tray. C, ThermaChoice III device elements. D, ThermaChoice III device inflated in uterine model with abnormal cavity. (Courtesy of Ethicon, Inc., Somerville, NJ. Reproduced with permission.)

- to accommodate the volume, causing a pressure reduction. Judicious addition of  $D_5W$  in small increments will likely be necessary to maintain proper balloon pressure.
- 6. After titration of pressure, allow approximately 1 minute to pass before activating the ablation process by pressing the "Start" button. There are integrated safeguards on the generator that assist the surgeon in avoiding or detecting some potential problems. If uterine perforation occurs during the balloon insufflation process, the pressure does not stabilize, thus rendering the start process inactive. Another cause of unstable pressure readings is a leak in the catheter, which should prompt the surgeon to reevaluate the integrity of the connections and the stability of the uterus. If the surgeon insufflates the balloon to a pressure greater than 220 mm Hg, the balloon may become damaged and rendered unusable by bursting a safety valve. The patient's safety is ensured with the ThermaChoice system in that there is no override process incorporated in the generator if there is any inclination to add more D<sub>5</sub>W during the process or start the process without all of the elements for ignition in place.
- 7. After the start button has been activated safely, a heating element located inside the balloon raises the temperature of the fluid to 87°C. The time to reach the required temperature takes anywhere from 15 seconds to 4 minutes, but averages around 40 seconds. Once the balloon reaches the required temperature, thermal coagulation of 3 to 5 mm of the endometrium by heat transfer through the balloon occurs. It is important that the surgeon hold the catheter steady and in the center of the uterus during the 8-minute ablation process. A variance in uterine pressure is a not uncommon occurrence because of uterine relaxation. The controller connected to the catheter monitors and displays catheter pressure, regulates temperature, and controls therapy time until the process has been completed. It then automatically shuts the unit off. The balloon is then deflated and withdrawn from the uterus after a 1-minute cooling period. Very detailed demonstrations are available at the ThermaChoice website (www. interact3d.com/modules/).
- 8. Withdraw the tenaculum and speculum and disconnect all cords connected to the catheter. The entire procedure can be

performed in less than 1 hour on an outpatient basis if local anesthesia and IV sedation are used. Mild to moderate uterine cramping may occur during the first day postablation. Otherwise, recovery is usually uncomplicated. Vaginal discharge or spotting may occur during the first week. Patients generally resume normal activities within 24 hours of treatment.

### **Common Errors**

- Improper assembly of unit and components
- Incomplete preoperative work-up
- Attempting to exceed the recommended 60 mL of fluid in the balloon
- Attempting to perform ThermaChoice ablation on a uterus sounding greater than the recommended 12 cm

## **Complications**

Complications are rare and less common than with traditional endometrial ablative techniques. Possible adverse events include uterine perforation, fluid overload in the balloon, perforation of the balloon (rare), and the balloon compromising cervical integrity (cervical overload).

## Postprocedure Management

Postoperative pain medications should be administered as needed, including NSAIDs, opiates, or acetaminophen. The patient should make a return appointment within 1 to 2 weeks and call if there are signs of fever, pain or infection, prolonged vaginal discharge, or bleeding. Normal activities can generally resume immediately; intercourse should be avoided for 2 weeks.

## Radiofrequency (NovaSure) Ablation of the Endometrium

## **Equipment and Supplies**

- NovaSure endometrial ablation device and radiofrequency controller
- Miller speculum (open sided)
- Hegar dilators in sizes up to 9 mm
- Dressing forceps
- Two single-tooth tenacula
- Uterine sound
- Paracervical block supplies (see Chapter 173, Paracervical Block)
- Optional instrumentation: 5.5-mm diagnostic hysteroscope, weighted speculum, Simms retractor, small Deaver retractor, 16-Fr straight catheter

Appropriate resuscitative equipment is necessary and varies depending on the setting and type of anesthesia administered.

Use of the NovaSure radiofrequency device (Cytyc Corporation, Marlborough, Mass) involves inserting a slender wand through the cervix (Figs. 156-4 to 156-6). A triangular, meshlike device (the electrode array) is then passed through the wand and expands to fit the uterus. Radiofrequency electrical energy is passed through it for about 90 seconds and the mesh and wand are then withdrawn. As with many other second-generation ablation techniques, it is quick and effective and does not require pretreatment to expand the uterus. The following description is as detailed as the procedural instructions given by the manufacturer. However, the manufacturer's website animation provides a superb simulation of the actual procedure (www.novasure.com/novasure-procedure/procedure-animation.cfm).

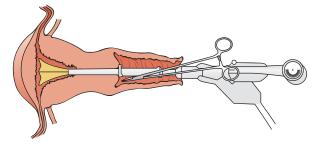

## **Procedure**

- 1. Repeat steps 1 to 3 from the hysteroscopic rollerball ablation section.
- Anesthetic administration is similar to that for the other second-generation techniques. It can be performed in the operating room under general anesthesia or with IV sedation with

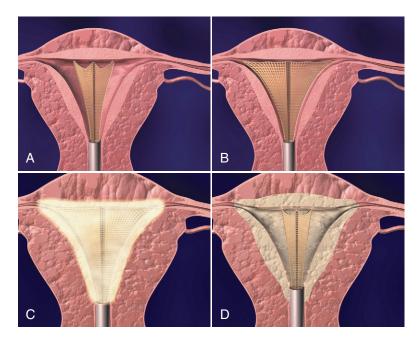

**Figure 156-4** The NovaSure Controller. (Courtesy of Hologic, Inc., and affiliates, Marlborough, Mass.)

- paracervical block. It can also be performed in the office with NSAIDs and a paracervical block.
- 3. Insert the untapered Hegar dilator until resistance is met at the internal os to measure *endocervical canal length*. Subtract this length from the original uterine sound length to obtain uterine cavity length. *This is a very crucial measurement*.
- 4. Diagnostic hysteroscopy is optional.
- 5. Squeeze the handles of the sterile NovaSure device into the locked position to open the mesh electrode array before inserting it into uterus to ensure that it deploys. Verify that the cornual width gauge found on the instrument is greater than 4 cm. On deployment of the device, the electrode array indicator light should no longer illuminate.
- 6. Unlock the device and retract the array into the protective sheath by pulling back the handle using the "bow and arrow" technique.
- 7. Adjust the cavity length (the total uterine cavity length on uterine sounding minus the cervical cavity length) using the length-adjusting feature on the handle of the device.
- 8. Dilate the cervix to 8 mm with tapered Hegar dilators.
- Slide the cervical collar onto the sheath in its entirety. Insert the device into the cervix while holding the handle until the distal sheath reaches the fundus.
- 10. Tap the fundus with the array while slowly squeezing the handles, which deploys the electrode array inside the uterine cavity.
- 11. Seat the device by maneuvering it laterally, medially, anteriorly, and posteriorly, rotating it clockwise and counterclockwise. Pull the device backward until a decrease in value is noted on the cornual width gauge. Advance toward the fundus at this point. Repeat until maximum width is gained as demonstrated on the cornual width gauge. Input the width and length measurements

**Figure 156-5** Fully expanded NovaSure device in vaginal cavity with fully expanded bipolar electrode in the uterine cavity. (Redrawn from Hologic, Inc., and affiliates, Marlborough, Mass.)

**Figure 156-6** NovaSure procedure. **A,** Step 1: The NovaSure bipolar electrode expands from the slender sheath to conform to the contours of the uterine cavity. **B,** Step 2: The system insufflates the uterine cavity with  $CO_2$  to perform the cavity integrity assessment. **C,** Step 3: NovaSure delivers bipolar radiofrequency energy for a complete and contoured ablation in approximately 90 seconds. **D,** Step 4: The electrode array is retracted into the sheath for easy removal, leaving the uterine lining desiccated down to the superficial myometrium. (Courtesy of Hologic, Inc., and affiliates, Marlborough, Mass.)

into the controller (the length is the total uterine cavity length on uterine sounding minus the cervical cavity length).

- 12. Use one hand to *stabilize the cervix* with the tenaculum while holding the device. Slide the cervical collar forward to create a seal.
- 13. Assess the cavity integrity by stabilizing the cervical collar, then stepping on the footswitch once to activate this function on the controller. Carbon dioxide is insufflated into the uterine cavity. When the uterine cavity is insufflated to 50 mm Hg for approximately 4 seconds, the control unit must recognize no evidence of perforation. The procedure cannot proceed if perforation is evident; there is no way to override the device.
- 14. Once the cavity integrity is established, the controller will signal that the ablation process is enabled. The operator then steps on the footswitch once to *activate the ablation cycle*. The cycle using radiofrequency power lasts at least 90 seconds and not over 2 minutes. The controller signals when the cycle is complete.
- 15. Remove the cervical sheath and retract the array carefully.
- 16. Remove all instruments and transport the patient to recovery.

## **Common Errors**

- Deployment problems with the device due to improper patient selection
- Errors in connecting and setting up the equipment properly
- Improper interpretation of measurement data, thus prolonging procedural time

## **Complications**

Perforation, thermal burns to adjacent tissue, prolonged bleeding, infection, prolonged pain (beyond the usual expected postoperative discomfort), pregnancy, and prolonged discharge are some of the most common complications encountered.

## Postprocedure Management

The usual analgesics of the surgeon's choice should be used. These include NSAIDs, opiates, and acetaminophen. There will be a vaginal discharge for 3 to 6 weeks. Uterine cramping will likely occur. The patient should return for a reevaluation appointment in 2 weeks and for possible complications such as prolonged bleeding, pain, fever, or septic symptoms such as fever and tachycardia.

## Cryoablation of the Endometrium

The Her Option Cryoablation System (American Medical Systems, Inc., Minnetonka, Minn) is another minimally invasive nonhysteroscopic method for endometrial ablation.

Cryoablation of the endometrium destroys tissue by the application of extreme cold through the use of the gas-cooled cryoprobe. Its operation is based on the Joule-Thomson principle, in which pressurized gas is expanded through a small orifice to produce cooling. Temperatures of  $-100^{\circ}$  C to  $-120^{\circ}$  C are achieved at the tip, producing an ice ball. As this ice ball grows, tissue that comes into contact with the portion of the ice ball that is  $-20^{\circ}$  C or colder is destroyed. Activation of the cooling process initiates efflux of gas through the cryoprobe; it expands at low pressure at the tip of the cryoprobe, causing an abrupt drop in temperature and freezing of the endometrium. The gas then is transported back to the compressor for recirculation.

A recently completed study directed by the FDA demonstrated the safety and effectiveness of the cryoablation system in controlling abnormal uterine bleeding. Cryoablation was found to be as effective as rollerball ablation, but is much easier to learn and causes less significant side effects. It is safer than rollerball ablation because it does not require distention of the uterus or the use of large amounts of fluid necessary with operative hysteroscopy. Moreover, cryoablation requires minimal anesthesia and can be performed in a physician's office, although the surgical suite is still an option if dictated by clinical circumstances.

The work-up and preparation of a patient for a cryoablation procedure is similar to that for rollerball ablation, except that all patients *must have an ultrasonographic examination* performed to determine whether they have endometrial polyps or myomas. If submucous fibroids or polyps are found in the uterine cavity, the tissue should be sampled to rule out a premalignant or malignant process. This is accomplished by hysteroscopy and D&C. If the submucous myomas are greater than 3 cm in diameter or extend over halfway into the uterine cavity, the patient is not a good candidate for cryoablation. This is because the depth of tissue destruction is characteristically 9 to 15 mm. In this case, the resectoscope should be considered to remove the myomas before ablation. Pretreatment with a GnRH agonist is not necessary. Tutorial materials and an excellent training video can be accessed online at www.heroption.com.

## Equipment and Supplies

The Her Option self-contained control console comes with an attached, slim 5-mm disposable cryoprobe with two-button control (Control Unit [CU]). The console also provides an audio-guided, step-by-step tutorial. A 3-L bag of 0.9% saline, a catheter that inserts into the machine, and a portable ultrasonography unit are also required.

## **Procedure**

- 1. Repeat steps 1 to 3 from the hysteroscopic rollerball ablation section.
- Provide the appropriate anesthetic. (This procedure may involve less pain because of the cryoanesthesia conferred by the instrument and procedure.)
- 3. Once the anesthetic is administered, a Foley catheter is inserted to *instill 300 to 400 mL of saline into the bladder* to facilitate ultrasonographic visualization of the uterus during the procedure.
- 4. Place the disposable CU over the cryoprobe. It is provided sterile, for single use only. A fuse in the disposable CU prevents function of the system if reuse is attempted. The "heat" button is used at the end of the each freeze cycle to thaw the probe away from the tissue for the next freeze cycle.
- 5. Dilate the cervix to 5.5 mm to accept the cryoprobe.
- Gently insert the cryoprobe into the uterine cavity (Fig. 156-7).
   The probe is provided with measurement markers enabling the surgeon to measure the uterine cavity. Confirm successful cannulation with ultrasonography.
- 7. Aim the CU toward one of the cornua and *inject 5 mL of saline into the uterus* through the accessory port on the cryoprobe. This will help to effect optimal tissue adherence to the cryoprobe during the freezing process.
- 8. Active freezing is initiated by pressing the "freeze" button on the CU (Fig. 156-8). Freezing continues until the user presses the freeze button again to pause freezing (freeze time will stop counting and resume when the user presses the freeze button again) or presses the heat button to begin heating, or until the safety time limit of 10 minutes is reached. The user presses the heat button to terminate the freeze. The heater cycles automatically to maintain a temperature of 37° C on the probe surface until the user pushes the freeze button again to complete a second freeze cycle.
- 9. The cornua are subjected to cryoablation first, with the process taking 4 to 6 minutes for each (Fig. 156-9). After the first cornu is finished, ultrasonography may be used to ascertain the depth of cryoablation. Ideally, the cryoablation process stops before the edge of the ice ball reaches the serosa. Ultrasonography also helps to assess the progress of the procedure and will help determine the number of passes required to effect successful

**Figure 156-7** Her Option cryoprobe tip. (Courtesy of CooperSurgical, Inc., Trumball, Conn.)

**Figure 156-8** Her Option P30 module. (Courtesy of CooperSurgical, Inc., Trumball, Conn.)

ablation. Uterine size also determines the number of passes required. When the tip of the cryoprobe cools to a temperature of less than -90° C, an ice ball ellipse 3.5 to 5 cm in size forms around the probe. The edge of the ice ball is approximately 0° C and is nonlethal to the endometrial tissue. The lethal temperature for the tissue is -20° C and is found approximately 1.5 cm from the edge of the ice ball. Again, ultrasonography can be used to assess the characteristic changes in the tissue that denote adequate destruction. After satisfactory destruction of the tissue of the second cornu is completed, the heat button is pressed to pull the CU away from the destroyed endometrium. The CU is then reactivated at the midline in the uterus in the same manner as for the cornua. The ice ball is monitored by ultrasonography to assess destruction. Again, the procedure takes from 4 to 6 minutes, depending on the depth of destruction. Because there is no distention medium and saline is injected to effect maximal contact, both anterior and posterior components of the uterine cavity may be destroyed simultaneously. Examples of the varied options for passes made with the CU include (1) one freeze for 6 minutes in both cornua and one freeze for 6 minutes in the midline; (2) two freezes in both cornua for 6 minutes; (3) two freezes in both cornua for 6 minutes and two freezes in the midline for 4 minutes; and (4) one freeze in the midline for 4 minutes and two freezes in both cornua for 6 minutes. The number of variations depends on the anatomy and desired clinical outcome as defined by the surgeon and the ultrasonographic findings.

Once adequate tissue destruction is achieved, remove all instruments and transport the patient to recovery or allow recovery in the procedure suite.

## **Common Errors**

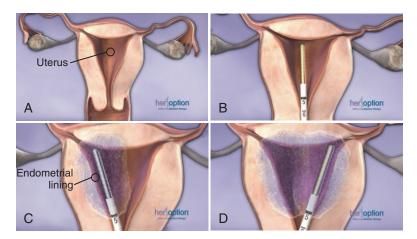

- Inadequate assembly of equipment, thus delaying procedural start
- Operator error causing failure of equipment to perform as expected
- Insufficient freeze time to provide adequate cryoablation
- Inadequate destruction of fibroid tumors

## Complications

Potential complications include adjacent tissue damage, perforation, prolonged bleeding, prolonged pain, and infection.

## Postprocedure Management

Cryoablation usually does not cause a great deal of pain because of the nature of the destruction. However, if postoperative pain does present, the usual pain medications of the surgeon's choice should

**Figure 156-9** Stages of cryoablation. **A,** Uterus before cryoablation. **B,** Insertion of cryoprobe. **C,** Cryoablation of right cornua. **D,** Cryoablation of left cornua. (Courtesy of CooperSurgical, Inc., Trumball, Conn.)

be used. An NSAID, opiate, or acetaminophen is appropriate. A follow-up appointment should be scheduled for 1 to 2 weeks. The patient should be instructed to call in the event of prolonged post-operative bleeding, pain, fever, or infection.

## **Hydrothermablation**

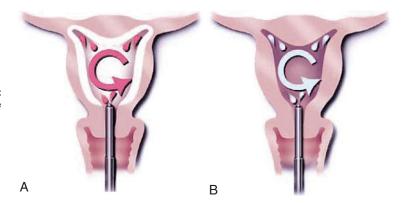

## **Equipment and Supplies**

- Hydrothermablation (HTA) control unit. The control unit has a
  microprocessor that relays a series of instructions noted on the
  monitor for system setup as well as providing leakage alerts. The
  microprocessor also monitors fluid loss and alerts the operator if
  a loss of 10 mL is detected at any time during the setup or ablation
  procedure. The control unit uses room-temperature saline to
  purge air from the delivery system.
- A 3-L bag of sterile 0.9% saline is suspended from an IV pole connected to the control unit (ideally 115 cm above the uterus to ensure good outflow pressure).
- A sterile procedure kit and an unsterile fluid management reservoir.
  The one-use sterile procedure kit consists of a cassette assembly, heater canister, a disposable HTA sheath that connects to the hysteroscope, and fluid tubing. Some institutions use the heater canister 10 times, repackaging and resterilizing the unit and marking the number of sterilizations before each use and subsequent disposal.
- A rigid hysteroscope of the surgeon's choice is also needed (the 12-degree scope is the most versatile). If one uses the 30-degree scope, care must be taken to avoid aiming the end of the scope toward the wall of the uterine cavity so as not to traumatize the
- A silicone tip that creates the closed-loop circulation system when attached to the HTA sheath is also needed.

## Procedure

- 1. Repeat steps 1 to 3 from the hysteroscopic rollerball ablation section.
- 2. With HTA, it is essential that the cervix **not** be dilated greater than 8 mm. It is also important not to use cervical dilating agents such as laminaria tents. If the cervix is dilated greater than 8 mm, the seal of the cervix around the sheath may be compromised, resulting in leakage. This may lead to thermal burns, which is a potential complication of this procedure.
- 3. Proceed with *paracervical block* (see Chapter 173, Paracervical Block).
- 4. Remove the HTA sterile sheath from its pouch and connect it using appropriate adapters (if needed) to the hysteroscope of choice. Be sure to use a hysteroscope with a diameter of less than 3 mm. This will ensure proper flow of the heated fluid from the HTA sheath.

- 5. Place the silicone tip attachment over the end of the sheath. This is crucial in maintaining the closed loop for circulating the heated fluid in and out of the uterus during the procedure.
- Have an assistant connect the inflow and outflow tubes to the pump mechanism on the machine. Tips are color coded to ensure correct placement.
- 7. Press the start button. This commences the procedure, and the unit circulates saline through all of the tubing, eliminating any residual air. This takes approximately 1 minute; the main unit displays a counter until this portion of the process is complete.
- 8. During the countdown phase, *all tubing connections and the sheath should be checked* for leaks, and the light source and hysteroscope unit can be assembled in their entirety.
- 9. The circulation of the proper amount of saline at the proper pressure is ensured by *placing the bag of saline 115 cm (45 inches)* above the patient's pelvic region. This provides approximately 50 to 55 mg Hg intrauterine pressure, ample circulating pressure but below the tubal ostia opening pressure of 70 mm Hg. The circulating function begins with the pressure created by the height of the saline bag. The sheath functions as the circulating conduit for the saline. The HTA control unit functions as an aspiration pump, returning saline from the uterus to the reservoir and heater canister on the control unit for heating and reheating.
- 10. Gently insert the hysteroscope-sheath unit under direct visualization and with saline flowing into the intrauterine cavity. This procedure requires an assistant to observe the ablation process and operate the ablation control unit. The intrauterine cavity is inspected at this point.
- 11. Once the cavity has been evaluated, the hysteroscope—sheath unit is withdrawn to the level of the internal os to ensure the ablation treatment area remains in the uterine cavity and does not extend into the cervix. A tight uterine seal is essential to avoid the potential complication of vaginal burns from leakage of fluid onto the vaginal mucosa. This can be effected by adding one or two tenacula to the cervix to tighten the seal.
- 12. Commence the ablation process by starting the fluid warming cycle. Once the fluid reaches 90° C (194° F; Fig. 156-10A), the ablation cycle begins as the microprocessor on the main unit is triggered. Ablation is performed under the surgeon's direct visualization until the approximately 10-minute cycle is completed. Tissue necrosis is usually appreciated to a depth of 2 to 4 mm after 10 minutes.
- 13. After the ablation cycle has ended, the control unit triggers a 1-minute cooling cycle to evacuate the superheated saline from the delivery system tubing. This must be completed before removing the hysteroscope—sheath unit from the cervix (Fig. 156-10B). Room-temperature saline flows into the uterus, which circulates the heated saline into the collection bag. When the cooling cycle

**Figure 156-10** Hydrothermablation. **A,** Heating component of the ablative procedure. **B,** Cooling component of the ablative procedure, showing circulation of saline.

is complete, the control unit displays a message indicating safe conditions exist for removal of the sheath from the uterus and cervix. Again, this prevents efflux of superheated saline into the vaginal cavity with subsequent burns to the area.

14. Before disassembling the unit, the team must wait for the entire system to cool down. This includes the canister, tubing, cassette, heater, and reservoir. This is indicated by a message in the control unit when the temperature in the heater canister falls below 45° C.

### **Common Errors**

- Improper assembly or construction of the system
- Inefficient dilation of the cervix
- Improper placement of IV tubing into the unit, thus decreasing saline pressure for HTA
- Hysteroscopy malfunction
- Improper cervical seal
- Removing the unit prematurely from the cervix before the cooling process is complete

## Complications

Potential complications include thermal burns from leakage of fluid into the peritoneal or vaginal cavity, perforation, postoperative infection, vaginal discharge (greater than expected), and abdominal cramping longer than expected.

## Postprocedure Management

Postprocedure management is the same as for thermal balloon ablation of the endometrium.

## **Microwave Endometrial Ablation**

The Microsulis (Denmead, United Kingdom) microwave endometrial ablation (MEA) device was approved for use in the United States in 2003. It uses microwave energy at a frequency of 9.2 GHz, at which the microwave tissue-heating effect penetrates to less than 3 mm. Heat may be thermally conducted another 2 to 3 mm, creating a total depth of tissue destruction of 5 to 6 mm. The chosen frequency for MEA ablates the endometrium to the basal layer. Treatment of the entire uterine cavity is achieved by sweeping the applicator tip across the endometrial lining of the uterus. Microwaves are emitted from the distal end of the MEA applicator tip, providing controlled heat to the adjacent tissue. The process creates a hemispherical pattern of destruction at the applicator tip; because uterine tissue has a robust water content, this results in the reduction of the microwave field amplitude by approximately 90% 3 cm from the applicator tip. Destruction beyond this point of high-intensity heat still occurs by thermal conduction. Thus, endometrial destruction is achieved by direct and conductive heating effects. MEA treatment is fully adaptable to most sizes, shapes, and conditions of the uterine cavity. The thermocouple at the tip of the MEA applicator allows the operator to monitor and control localized

temperatures, giving the most effective and maximal dispersion of microwave energy throughout the uterine cavity to achieve a complete ablation.

Prerequisites that need to be considered before proceeding with MEA include uterine cavity length less than 12 cm and uterine wall thickness greater than 12 mm. If present, fibroids in the uterine cavity should be less than 5 cm in diameter and must not obstruct the progress of the transcervical applicator. Repeat procedures are not recommended. Irregular cavities can be considered for treatment.

## **Equipment and Supplies**

The Microsulis device is equipped with a disposable transcervical applicator connected to an ergonomic handle designed specifically for a "sweeping" technique. The controller system permits real-time information monitoring of localized temperatures from the thermocouple at the tip of applicator. A diagnostic hysteroscope of the surgeon's choice, with all of its attachments, is necessary.

## **Procedure**

- 1. Repeat steps 1 to 4 of the hysteroscopic rollerball ablation section.
- Proceed with hysteroscopy to ascertain/confirm positive or negative preoperative ultrasonographic findings. This will also help to ensure there are no perforations or anatomic obstructions that will obstruct probe placement in the uterine cavity.
- 3. Insert the applicator to the midline of the fundus. The applicator has centimeter markings on its side, enabling the surgeon to make sure the original uterine sounding measurement is the same as observed with the applicator. The microwave generator is activated by depressing the footswitch.
- 4. Once the temperature reaches 70°C to 80°C, begin the sweeping motion in the fundal region, starting in one cornu then moving to the opposite cornu. Then move the applicator downward through the rest of the uterine cavity. The ablative process is effected by microwave energy emitted from the tip of the device, where a thermocouple allows real-time temperature monitoring during the treatment process. A second sensor located at the base of the applicator provides a temperature gradient. The intraoperative temperature is displayed digitally on the control unit, which has a graphic band highlighting the 70° C to 80° C level. This enables the surgeon to monitor the process of effective ablation and prompts him or her to maneuver the applicator to maintain the temperature within the therapeutic band. It must be understood that endometrial destruction takes place even when temperatures are not ideal. The ideal 5- to 6-mm depth of destruction is not achieved with temperatures less than the indicated 70° C to 80° C range. The device is moved back and forth and gradually downward in a sweeping manner, as described. The temperature is observed on the system monitor. As the applicator is retracted further, a yellow marker 4 cm from the tip of the applicator wand helps to prevent treatment of the endocervical

- canal, which could result in cervical stenosis. The usual time for the procedure is approximately 2 to 4 minutes and depends on uterine length and thickness.
- The applicator is then withdrawn gradually from the uterine cavity.

### **Common Errors**

Most errors are user related. Some of the more common issues include the following:

- Improper connection of the system parts
- Poor preoperative dilation of the cervix
- Triggering the procedure before the applicator is fully deployed
- Continuing with ablation past the yellow marker on retraction of the applicator, thus damaging the endocervical canal

## Complications

The most common complications have been uterine perforation, serosal thermal injury to adjacent organs, and escape of thermal energy outside of the cervical canal. One of the best general preventive measures is to perform hysteroscopy before the procedure. This alerts the surgeon to any anatomic differences or anomalies that may increase the risk of complications during the ablation procedure.

The MEA system has safety mechanisms that help to prevent complications before the procedure starts. The system will prevent initiation of the procedure if the applicator insertion depth is greater than the original sounding measurement. An increase in the measured length of the applicator raises the concern of possible misplacement of the applicator in a perforation or commencement of the procedure before full insertion of the applicator in the uterine cavity.

The system also has a temperature alarm when the surface temperature of the applicator reaches 85° C. The system automatically shuts down if the temperature reaches 90° C.

## Postprocedure Management

Postprocedure management is the same as for thermal balloon ablation of the endometrium.

## **FINAL COMMENTS**

Table 156-1 summarizes and compares the different second-generation techniques of endometrial ablation.

The procedure of endometrial ablation enables physicians to serve patients who have abnormal endometrial bleeding. It has evolved from a surgical suite procedure with the hysteroscope into a potentially office-based service that provides convenience, safety, and the avoidance of hysterectomy. The particular approach depends on the physician performing the procedure and his or her training, level of expertise, and comfort level with the service performed. Although the results from the newer procedures are similar to those with the traditional ablative techniques, complications are fewer and recovery is quicker with the newer methods.

## **PATIENT AND PHYSICIAN EDUCATION GUIDES**

Each company listed in this chapter has its own brochure for physicians and patients. In addition, there may be descriptive instructional videos available. The company websites should be reviewed for examples.

## **CPT/BILLING CODES**

- 57800 Dilation of the cervical canal, instrumental (separate procedure)
- 58353 Endometrial ablation, thermal, without hysteroscopic guidance

- 58356 Endometrial cryoablation with ultrasonic guidance, including endometrial curettage, when performed
- 58555 Hysteroscopy, diagnostic (separate procedure)
- 58558 Hysteroscopy, surgical with sampling, with or without
- 58561 Hysteroscopy with removal of leiomyomata
- 58563 Hysteroscopy, surgical; with endometrial ablation (e.g., endometrial resection or electrosurgical ablation or thermoablation)
- 59200 Laminaria insertion

## **ICD-9-CM DIAGNOSTIC CODES**

- 626.2 Excessive or frequent menstruation, menometrorrhagia, menorrhagia
- 626.8 Dysfunctional uterine bleeding

## **ACKNOWLEDGMENT**

The editors wish to recognize the many contributions by Duane E. Townsend, MD, to this chapter in the previous edition of this text.

# TREATMENT OF THE ADULT VICTIM OF SEXUAL ASSAULT

Olasunkanmi W. Adeyinka

Current statistics indicate that a sexual assault occurs every 4 seconds in this country. One in every four women will be sexually assaulted in her lifetime. But not only women are affected: almost 10% of assault victims are male. Sexual assault is the fastest-growing, most frequently committed, and most under-reported violent crime in the United States.

Sexual assault is under-reported for many reasons, including societal misconceptions about the victims of sexual assault, feelings invoked by such an assault, and the burden of reporting an assault. Misconceptions persist, despite enhanced public education, that individuals who are assaulted may have encouraged the act by their behavior, dress, lack of resistance, or previous promiscuity. Complex law enforcement and health care systems are often perceived as being impersonal and nonsupportive. An estimated 75% of victims know their perpetrators, possibly enhancing feelings of embarrassment, guilt, and fear of retribution. These feelings and misconceptions combined with inadequate support systems often prevent a victim from reporting a sexual assault.

The purpose of the medical evaluation after sexual assault is to assess the patient for physical injuries or possible disease, to document injuries, and to collect the necessary evidence. The remainder of the encounter should be used to treat any injuries, to prevent pregnancy and disease, and to find the proper support services for the victim. The examination and treatment should be completed as soon as possible after the assault, especially the collection of evidence. Although an evaluation within 48 hours is preferred, victims are encouraged to see a clinician even if more than 72 hours have elapsed (this still allows a clinician to treat and prevent many problems).

Collaboration between hospitals, community services, and local law enforcement agencies for the establishment of protocols is very helpful, and such protocols will ease victims' pain and suffering. Primary care clinicians can be instrumental in ensuring that this collaboration takes place. Such collaboration is effective at not only streamlining the evaluation process but for easing the burden of reporting. Some institutions offer 24-hour availability of specially trained and experienced volunteers, such as a nurse on every shift. These volunteers can provide the victim continuous support during the cumbersome process of answering questions and the examination. They can also act as witnesses for the chain of evidence. A supportive volunteer system can offer such simple things as a change of clothing (victims often need to leave their clothing as evidence), which are hugely appreciated by victims.

## **INDICATION**

Sexual assault requires treatment.

**NOTE:** Sexual assault is any form of nonconsenting sexual activity. It encompasses all unwanted sexual acts, from fondling to forcible penetration.

## **CONTRAINDICATION**

A lack of patient consent contraindicates treatment.

## **EQUIPMENT AND SUPPLIES**

- Camera and film
- Wood's light or other high wavelength light
- Sexual assault kit: Most emergency departments have a standard kit that contains a protocol for care and all the necessary specimen containers. These should be in compliance with and fulfill state laws for sexual assault (Table 157-1). In general, kits should contain the following:
  - Information for the victim
  - Consent form for the examination
  - Instructions, checklist, and chain of custody form
  - History and physical examination forms
  - Diagrams for use in documentation of injuries (Fig. 157-1)
  - Specimen containers, equipment, and labels
- Colposcope (optional)

## PREPROCEDURE PATIENT EDUCATION

If a patient calls before presenting to the emergency department, first make sure that the patient is safe. If not, encourage the patient to call the police. Next, encourage the patient not to take a bath or remove the clothing worn during the assault. If possible, they should postpone urinating, defecating, brushing their teeth, or drinking anything until samples are collected. Also, ask them to bring a change of clothing. Patients should sign for informed consent before starting the evaluation (see the patient consent form available online at www.expertconsult.com).

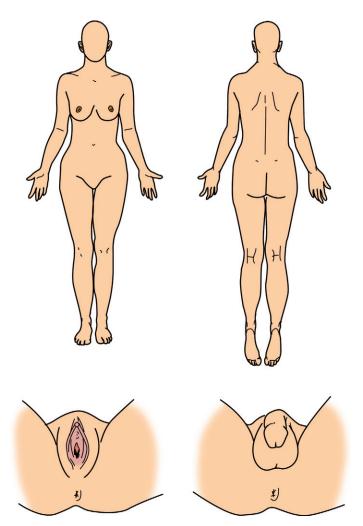

Explain the process of the evaluation to patients. Let them know that you will explain every step of the examination before performing it. Even if they may not want to report the assault, a very thorough examination is necessary in case of a later change of mind. Continue to reassure patients that they are safe and that someone else will always be in the room to comfort them during the evaluation.

## **PROCEDURE**

1. Open the sexual assault kit. Once the kit is opened, the chain of evidence must be maintained and evidence must not be left unattended. Signatures of those in attendance must be documented on the form for any and all evidence collected. (See Chapter 158, Management of the Young Female as a Possible Victim of Sexual Abuse, Fig. 158-8, for a sample chain of evidence form.) The kit should be labeled as a biohazard. After the patient has signed the consent form, proceed with taking the history.

### Sexual Assault Kit Equipment **TABLE 157-1 Contents Purpose** Two urine containers Urine for microscopic urinalysis, pregnancy test, and drug screen Fingernail clippers, file, and envelope Fingernail clippings and scrapings Forceps, scissors, two envelopes Pubic hair trimming in one envelope, head hair trimming in other envelope Plastic comb, large paper towel, two envelopes Pubic hair combing in one envelope, head hair combing in other envelope Vaginal speculum, aspiration pipette, red-topped test tube and stopper Aspiration of vaginal contents Four cotton-tipped swabs and a test tube or envelope, one slide Vaginal (or penile) swabbing, and smear (same for rectal swabbing and smear if indicated) Saline, 10 mL; two aspiration pipettes and bulbs; two test tubes, two slides Vaginal washing (and rectal if indicated using second pipette and test tube) Cervical scraper, brush, slides, Pap smear fixative Thayer-Martin plates and Chlamydia cultures and/or sample tubes for Gonorrhea and Chlamydia evaluation (positive cultures are the gold gonorrhea/Chlamydia enzymatic probes standard for court, but probes have greater sensitivity) Four cotton-tipped swabs and a test tube or envelope, one slide Oral swabs and smear Two cotton-tipped swabs and a test tube or envelope Saliva collection for secretor status Three red-topped test tubes and stoppers, tourniquet, nonalcohol swab to Blood samples prepare skin, syringe and needle Labeled paper bags Collection of clothing and dried body fluids Necessary and helpful forms Information, consent, and documentation Patient education handout Consent form History and physical examination form Diagrams for documentation of injuries Chain of custody form Any necessary instructions Checklist

<sup>\*</sup>Contents should be refrigerated after collection.

**Figure 157-1** Traumagram. Mark and label locations where there is evidence of trauma. (From Botasch AS, Braen GR, Gilchrist VJ: Acute care for sexual assault victims. Patient Care 28:112–137, 1994. Copyright Marcia Hartsock, Artist.)

## History

2. The history should be taken in a quiet room, with a witness present, after the patient has been assured that she or he is safe. Be cautious about the terms used in stating patient complaints. Avoid use of the word "rape" because this is a legal term. Instead, state the patient complaint as being a "sexual assault." Also, try to avoid the phrases "why didn't you ..." or "you shouldn't have ..." or "Did you do anything to lead them on?" In fact, try to avoid the words "why" and "alleged" altogether; "why" implies blame and "alleged" implies disbelief.

Questions should be directed to the victim in a nonjudgmental way, and the patient should be allowed to talk about the assault at a comfortable pace, using her or his own words. It is important to observe nonverbal communication that may indicate a need for further questioning. Supportive terms worth using include "I'm glad you're alive," "You did what you needed to survive," "I'm sorry this happened to you," and "It was not your fault." Allow the victim to express her or his feelings. To build rapport, it may be worth obtaining the medical and sexual history before obtaining the assault history.

**NOTE:** If you have a long-term relationship with the patient, the patient may prefer to be examined in your office. However, in many jurisdictions, legally admissible evidence of a sexual assault cannot be collected without using the kit and other resources that are often available only in the emergency department. It is important for practitioners to know the assault and rape laws in their state so that they can comply with any legal requirements.

## Medical and Sexual History (Gynecologic History for Women)

- Medical disease, if present, should be documented.
- Last voluntary sexual encounter up to 1 week before the assault
  and the race of that individual should be documented. If the
  encounter is less than 48 hours ago, blood and fluid samples may
  be requested from that individual at a later date.
- The victim's alcohol and drug intake should be documented.
- For women, the date of the victim's last menstrual period, her contraceptive use, pregnancy history, use of tampons, and any previous episode of gynecologic infection or pelvic surgery should be documented.

## **Assault History**

An accurate but brief description of the assault is crucial for proper collection and analysis of the physical evidence. This includes documenting the following:

- Age and identifying information for victim, and assailant(s), if available.
- Date, time, and location of the alleged assault.
- Details of sexual contact, such as actual or attempted oral, rectal, or vaginal penetration of the victim. Attempt to determine whether there was an ejaculation, digital penetration, or penetration with foreign objects. It should be documented whether a tampon was present, or if a lubricant, contraceptive foam, a spermicide, or a condom was used. If any of these are unknown, that should be documented.
- Type of physical restraints used, if any, and whether there were any threats, weapons, drugs, or alcohol involved. Was the assailant injured during the assault?
- Activities of the victim after the assault, such as changing clothes, wiping, washing, bathing, douching, dental hygiene, urination, vomiting, smoking, eating, drinking, or defectation.

## **Physical Examination**

Having a trained, experienced volunteer in the room in addition to the nurse may help distract the victim from her or his

- emotional and physical pain during the examination. The physical examination and collection of evidence are performed congruently. Carefully examine the entire body and photograph or make drawings of the injured areas (see Fig. 157-1). The clinician should search for bruises, abrasions, or lacerations about the head, neck, back, buttocks, and extremities. A victim who was choked may have petechiae on the face and conjunctiva. Physical trauma may be greater in sexually assaulted men, perhaps because only those who have been more seriously injured are likely to report the crime.
- 4. Examine the oral cavity. Broken teeth, a torn frenulum of the tongue or lip, or pharyngeal trauma may indicate that the mouth was forced open. Using two swabs simultaneously, swab the oral cavity and along the teeth for evidence of semen. Do not moisten the swabs before sample collection.

Repeat with two additional swabs. Prepare one smear on the slide by gently smearing the swabs over the surface. Allow the swabs and smear to air dry. Place swabs in envelope or test tube provided.

5. The victim's clothing should be collected and placed in a paper bag that is sealed and signed. Allow any wet clothing to air dry before packaging. If additional bags are needed, use only new paper (grocery-type) bags.

It may be helpful to photograph the patient before she or he disrobes. Semen may appear as flaking, crusty stains on clothing and will fluoresce under a high wavelength light. Have the patient disrobe while standing on paper from the examination table. Each item of clothing should be placed in a separate paper bag. Do not use plastic bags for clothing collection because they promote bacterial growth on blood or semen. Use gloves when touching the victim's clothes to avoid contaminating the evidence with your DNA or blood type from sweat.

- 6. For women, a pelvic examination should be performed to complete the physical examination. Lesions around the vulva or rectum may be present because of trauma from a hand, penis, or other foreign body. Superficial or extensive lacerations of the hymen and vagina, injury of the urethra, and, occasionally, rupture of the vaginal wall may be present. Swab and preserve any semen for later DNA analysis. Although historically recommended and still used in many locations, a Wood's lamp does not cause semen to fluoresce more than other commonly found substances. Alternative light sources with a higher wavelength may be more effective than the traditional Wood's lamp. The procedure is as follows:
  - Lubricate the speculum with water. Standard lubricants may adversely affect the results of the acid phosphatase test and alter sperm motility. Examine the vaginal wall and cervix for abrasions, ecchymoses, and lacerations. A colposcope may be helpful to document any microtrauma to the cervix or vagina. It can also be used to take photographs. The cervix should be swabbed and cultures and probes sent for gonorrhea and chlamydial infection. Four swabs should be used and a smear prepared in a manner similar to the oral swabs. The swabs should be allowed to air dry before sealing.
  - A Pap smear should be performed. Intact spermatozoa may be seen several days later on a Pap smear.
  - Any fluid from the posterior fornix should be aspirated and examined under the microscope. A sample of the aspirated fluid should be saved for DNA testing, as well as for testing for acid phosphatase and blood group antigens.
  - If no secretions are visible, a small amount of saline (about 5 mL) may be used to lavage the cervix and posterior fornix. Aspirate this fluid and save while using some to prepare slides. Examine the slides under the microscope for spermatozoa. Lavage with normal saline may enhance motility of spermatozoa for up to 2 hours. Motile sperm from the vagina imply intercourse within the past 6 hours (rarely within the past 12 hours) and their presence should be documented.

Immotile sperm imply intercourse within the past 12 to 18 hours (in rare cases, up to 24 hours). In addition to examining for spermatozoa with a wet smear, the slide should be examined for *Trichomonas*, bacterial vaginosis, and the presence of any *Candida* species.

- 7. The victim's pubic hair should be combed to detect foreign bodies, as well as for perpetrator pubic hair samples. If present, 15 to 20 perpetrator hairs should be collected as part of the evidence. In a separate container, 15 to 20 of the victim's trimmed pubic hairs should be saved. This process should be repeated for head hair, using separate specimen containers.
- 8. Bimanual and rectal examinations should be performed. Anal assault is more common in men. Look for erythema, edema, bleeding, mucosal tears, fissures, a hematoma, or sphincter laxity or spasm. The digital rectal examination is usually sufficient if nothing suspect is palpated and bleeding is absent or insignificant.
- 9. Anoscopy or proctoscopy are difficult for the patient, but may be required if you suspect a tear. The rectal area should be swabbed for *Chlamydia*. If anal intercourse is known to have occurred, four anal swabs should be used and a smear prepared in a manner similar to the oral swabs. Anal swabs can be moistened with sterile normal saline before using, if necessary. They should be allowed to air dry before sealing. (Penile swabs and smears can be performed in the same manner by swabbing the outside of the penile shaft.)

Next, wash the rectal vault with 5 to 10 mL of normal saline introduced through the anus with the hub of a syringe. Allow the saline to stand for 5 to 10 minutes, then aspirate and preserve as evidence. These samples can be examined for motile sperm, immotile sperm, and acid phosphatase. Fecal contamination precludes their use for blood group antigen analysis.

**NOTE:** Pelvic, rectal, and proctoscopic examinations should be done gently and with careful explanation because the victim not only may experience severe discomfort because of the local trauma but may experience flashbacks.

## **Laboratory Tests**

- 10. Obtain fingernail clippings and scrapings. These may harbor bits of the assailant's blood, skin, or hair. Photographs of bite marks may also be used to match dental records.
- 11. Saliva samples should be taken. The victim should not be allowed to smoke or eat for 30 minutes before taking a sample. If there is trauma to the mouth, this procedure should be delayed until the wound is healed. The swabs should be allowed to air dry before sealing. They should not be removed from the victim's mouth by anyone other then the victim or the examiner.
- 12. Guided by the history of the assault, the victim's symptoms, and any local protocol, determine which laboratory tests are appropriate. Recommended laboratory tests in all cases of sexual assault include the following:
  - A Venereal Disease Research Laboratory (VDRL) test for syphilis or rapid plasma reagin (RPR) test should be obtained at the initial visit and repeated at 6 weeks, 3 months, and 6 months.
  - Hepatitis B serology should be checked (hepatitis B surface antigen and antibody and the hepatitis B core antibody).
  - Serology for human immunodeficiency virus (HIV) should be obtained at the initial visit and repeated at 6 weeks, 3 months, and 6 months after exposure, after proper patient counseling.
  - The patient's blood type should be determined from blood or saliva swabs.
  - For women, a urine or serum β-human chorionic gonadotropin (hCG) pregnancy test at the initial examination is needed to rule out existing pregnancy.

### **Treatment**

- 13. Treatment of major or life-threatening injuries should occur before initiating the evaluation. After the patient is stable, treatment of other physical injuries should depend on the type sustained.
- 14. Sexually transmitted infection (STI) prevention
  - Antibiotic prophylaxis: The current recommendation for the treatment of trichomoniasis, bacterial vaginosis, gonorrhea, and chlamydial infection is 250 mg of ceftriaxone intramuscularly and 2 g of metronidazole orally and either 100 mg of doxycycline twice daily for 7 days or 1 g of azithromycin once. Doxycycline should not be prescribed for pregnant patients.

This regimen will probably treat incubating syphilis. Although the overall risk of acquiring an STI from a single sexual encounter is only 5% to 10%, the aforementioned treatment should be prescribed for all victims of sexual assault.

- Hepatitis B prophylaxis: If the patient has not been immunized, hepatitis B virus vaccine should be given at the initial visit, then repeated at 1 and 6 months. Hepatitis B immunoglobulin (HBIG) 0.06 mL intramuscularly should be offered if the assailant is thought to be in a high-risk group for hepatitis B and the victim has experienced vaginal or anal bleeding from the assault. The same dose can be repeated in 1 month if the victim's serology is negative.
- HIV prophylaxis is not universally recommended. However, it should be understood that if the assailant cannot be apprehended and tested (most cases), the victim's infection status may not be known for 6 months. Treatment should be tailored to the patient's needs after counseling for medication costs and potential toxicity.
- Tetanus prophylaxis is indicated for anyone not immunized in the past 5 years.
- 15. For women, if the pregnancy test is negative, pregnancy prevention should be offered. See Chapter 129, Emergency Contraception, for available methods and dosing. These treatments are most effective for prevention of pregnancy if used within 72 hours of intercourse.

**NOTE:** Because up to half of all victims do not report for their follow-up visits, it is very important to perform adequate prophylaxis on patients during the initial visit.

## Follow-up

16. The patient should have a follow-up visit with a clinician within 72 hours to again document bruising and to evaluate the results of cultures if prophylactic antibiotics were not given. HIV and syphilis testing should be repeated at 6 weeks, 3 months, and 6 months. Follow-up counseling referrals should be made at the first visit. An additional follow-up visit should be made at 1 to 2 weeks to monitor patient progress (and to evaluate for pregnancy in women) as a result of the assault. If the patient did not receive prophylaxis for infection, STI testing should be repeated at this 1- to 2-week follow-up visit. If the patient received prophylaxis, repeat testing is indicated only if the patient is symptomatic. For women who are pregnant, counseling can be initiated and appropriate options for care can be discussed.

## POSTPROCEDURE PATIENT EDUCATION

Sexual assault is associated with major emotional and psychologic sequelae. Most women go through the three stages of rape trauma syndrome: (1) trauma (e.g., fear of being alone, fear of men, sexual problems, depression); (2) denial (not wanting to talk about it); and

(3) resolution (dealing with fears and feelings, regaining a sense of control over life). During the first two stages, patients may experience flashbacks, numbness or constriction of feeling, or hypervigilance. Mood swings, irritability, and anger are common and may indicate signs of healing. Insomnia, tension headaches, anorexia, fatigue, nausea, abdominal pain, and genitourinary symptoms are not uncommon. The last stage may take years to reach. The patient should be aware that should the case go to court, it may be necessary to gather additional evidence at a later time. Adequate follow-up and a counseling referral are an essential component of management. Men go through similar stages and need similar counseling.

Patients should receive a written outline of what was performed with the initial evaluation and what treatments were provided. They should also be given a written list of specific instructions and follow-up appointments. It should be written because most assault victims will not remember the evaluation and treatment they received, much less the instructions they were given after the treatment. Many communities have sexual assault centers that will provide advocates and support personnel for the victims during medical visits and for follow-up appointments. If this is not available or feasible, after obtaining the victim's permission, a trained counselor should be consulted. The most important contributing factor to the patient's recovery is contact with a trained advocate or counselor within the first 72 hours of a sexual assault.

The Rape, Assault and Incest National Network (RAINN; phone: 1-800-656-HOPE; website: www.rainn.org) can assist with finding local agencies and counselors trained to assist sexual assault victims.

## **ADDITIONAL RESOURCES**

See the patient education and consent forms available online at www.expertconsult.com.

## **CPT/BILLING CODE**

Use E/M codes for established or new patients for the noncolposcopic portion of the examination.

57452 Colposcopy

In some states, the law enforcement agency is required to pay for the evidence collection examination in the case of a reported sexual assault. The patient should sign a consent form to allow the law enforcement agency to be billed.

## **ICD-9-CM DIAGNOSTIC CODES**

878.4	Open	wound.	vulva.	without	mention	of	comr	lication

# MANAGEMENT OF THE YOUNG FEMALE AS A POSSIBLE VICTIM OF SEXUAL ABUSE

David B. Bosscher

Sexual abuse is so common that primary care clinicians should consider it as a possibility even during routine office visits. The prevalence is estimated to be 22.3% for girls and 8.5% for boys. Although child advocacy centers are increasingly available in many regions and communities, the generalist clinician is often the critical first line of evaluation.

In young females, common initial complaints include itching, redness, burning, irritation, discharge, or bleeding at the vagina. The abuse may be disclosed initially or discovered later. Occasionally, the abuse will be discovered when a parent wants a child examined after their use of sexually explicit language, demonstration of a sexual act on their doll, or other overtly sexual behavior. Because children may be exposed to sexually explicit media, the examiner must carefully sift through such allegations and concerns. Often the complaints are nonspecific and parents hope that a medical test can prove or disprove abuse. Unfortunately, in the majority of cases, children are seen long after the incident may have occurred. If, however, the alleged incident took place within 72 hours of complaint, immediate examination using a carefully structured protocol (e.g., a rape kit; see Chapter 157, Treatment of the Adult Victim of Sexual Assault) is mandatory.

A careful physical examination for children with allegations of sexual abuse is imperative, either in the clinician's office or through a regional child advocacy center. Nonetheless, only about 4% of physical examinations result in positive findings. A negative finding does not negate the claim of abuse, but does make interviews with social workers and other trained interviewers critically important to sort out allegations.

Although this chapter focuses on females, it is not meant to deny the possibility of abuse in males. If abuse is suspected in a young male, many of the same principles apply. It is important to know local laws regarding collection of evidence because they vary by location. The examiner should be certain to follow local standards for collection of forensic specimens.

## **INDICATIONS**

- Suspicion of sexual abuse after initial questioning or preliminary physical examination
- Referral from teacher, parent, or other responsible person alleging sexual abuse

## **CONTRAINDICATIONS**

- Lack of the instruments or supplies needed to carry out the examination
- · Lack of forms to preserve the chain of evidence

- Lack of a witness for the examination to preserve the chain of evidence
- Lack of consent to examine or treat a minor if a parent or guardian is not present

## **EQUIPMENT**

- Either a hand-held lens with an adequate examination light or a colposcope to examine details. One major benefit of a colposcope is that it allows the clinician to use both hands for the examination. If a hand-held lens is used, an assistant will be needed.
- Camera (helpful but not mandatory).
- A rape kit should be available in case it is necessary to document rape. If alleged sexual contact was within the past 72 hours, consider using the rape kit to collect evidence in an organized manner (see Chapter 157, Treatment of the Adult Victim of Sexual Assault).

## **Equipment on a Mayo Stand**

- Room-temperature culture media for gonorrhea or culture transport media from your reference laboratory
- Chlamydia and herpes culture media or culture transport media from your reference laboratory
- Materials for wet prep and potassium hydroxide (KOH) prep
- Cotton swabs, calcium alginate swabs (Calgiswab) or equivalent

**NOTE:** Do not use current available DNA probes for sexually transmitted infection (STI) testing in examinations for sexual abuse. As of October 2009, the package insert specifically states: "Do not use for medicolegal purposes or in sexual abuse cases." Although the technology may be better, and the DNA probes may be the standard of the future, they should not be used in these cases at present.

## PREPROCEDURE PATIENT PREPARATION

Explain the entire procedure to the caregiver and the child at a language level that both will understand. The child needs to know that she will be asked a lot of questions and that some may seem "silly." Explain that after the questions, the child will be examined.

It is often helpful to allow a young girl to maintain her sense of control over the process. After establishing rapport with the child, assure her that she will be allowed to be as active a participant as possible. If possible, she should know that she will be asked for permission before proceeding with any part of the examination.

Issues of privacy and confidentiality are important when examining older children. Although most young girls will prefer to have a parent, usually the mother, in the room at all times, in some cases it will be helpful to later spend time alone with the child. When alone with an examiner, a child may disclose abuse or other concerns. Letting her and the parent(s) know ahead of time (before the examination) that the clinician will be spending time alone with her may increase her comfort. Allowing that time alone may give her a greater sense of control and a feeling of responsibility for her own health. Consideration should be given to having a second person in the room with the patient and examiner at all times to serve as an assistant, chaperone, and witness. If the examiner is male, having a female assistant in the room may make the patient more comfortable.

Parents should be reassured that the child's hymen will not be altered in any way by the examination. Anatomic diagrams may be helpful for demonstration.

## **TECHNIQUE**

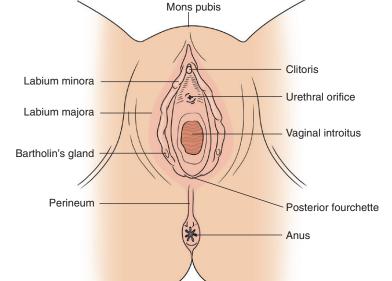

## Taking the History

- Assuming that a social worker or trained interviewer is responsible for taking a detailed history, the primary care clinician should take sufficient history to perform all pertinent portions of the examination. If no trained interviewer is available, a complete history should be taken in an unhurried and comfortable setting. Consider setting aside separate visits for the history and the physical examination.
- 2. Take some time to establish rapport. Ask about the current family structure, recent life changes, and which activities she enjoys, as well as about school and friends. Take notes while obtaining the history. It is often complicated. Obtain the names of persons potentially involved.
- 3. Document the descriptions of any potential sexual abuse in the child's own words. When the meaning of a word is unclear, ask clarifying questions. Document the meaning of the word in her terms. For example, if the child mentions sex, ask her what that means (e.g., because of depictions on television, children often think that sex means just being naked and in bed with another person).

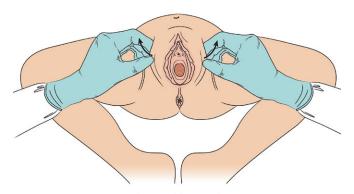

- 4. Do not be any more leading in questioning than is absolutely necessary. Begin with very general questions and go to more specific ones if the child does not offer sufficient information. For example, ask "Has anyone touched you in a way that made you feel funny or bad?" before asking "Has anyone touched your bottom?" Leading questions can not only misdirect the child and, subsequently, the examiner, they can also be neutralized by a defense attorney.
- 5. Do not allow the caregiver(s) to adopt a coaching role. Such a role may negate the clinician's testimony as well as the child's.
- 6. Young children have an incomplete concept of numbers and time. They often cannot tell how many times something occurred, but can often specify in general terms: "a lot," "once in a while," or "one time." Likewise, regarding time, small children do not understand the difference between "3 months ago" and "8 months ago."

## Preparing for the Vaginal Examination

- Again, take time to establish a comfortable setting. A childfriendly, compassionate medical assistant or nurse can be very helpful in using a toy, book, or stuffed animal to distract the child during the examination.
- 2. Explain the examination to the caregiver and the child at a language level they will comprehend. This is an important step toward reinforcing the child's sense of control over the examination. Begin by describing familiar portions of the examination ("I'm going to listen to your heart and then feel your tummy"). Then simply state that you are going to examine her genitalia ("Then I'm going to look at your bottom").
- 3. Explain to the child that the most important part of the examination is when the examiner merely "looks" around and that it is important for her to communicate with the examiner during the examination. Reassure the child that the examination should not hurt.
- 4. Perform the physical examination except for the vaginal–rectal portion. The examination should proceed from the least to the most intrusive while gaining the confidence of the child with each step.
- 5. Before performing the vaginal examination, it is helpful to recall normal anatomy (Fig. 158-1).

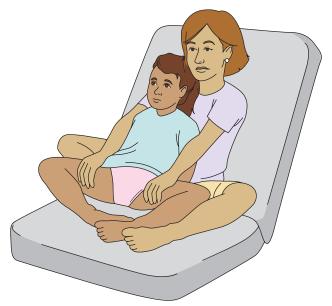

**Figure 158-1** Anatomy of genitalia in prepubertal girl. (From Dieckmann RA, Fiser DH, Selbst SM [eds]: Illustrated Textbook of Pediatric Emergency and Critical Care Procedures. St. Louis, Mosby, 1997.)

**Figure 158-2** Frog-leg position for examining labia. Note gentle traction on posterior labia to enhance visualization. (From Dieckmann RA, Fiser DH, Selbst SM [eds]: Illustrated Textbook of Pediatric Emergency and Critical Care Procedures. St. Louis, Mosby, 1997.)

## **Performing the Vaginal Examination**

- 1. Talk constantly ("verbal anesthesia"). A calm, quiet, confident voice can be reassuring. A relaxed and unhurried approach may decrease the child's anxiety. Having the parent sit close by or hold the child's hand may also provide comfort. If the child is provided a hand mirror, it may distract her, promote education, and allow her to participate more actively in the process.
- 2. Tell the child that it is acceptable to undress because she is in a clinician's office.
- 3. Frog-leg examination
  - Begin with the frog-leg examination. The child is supine with knees apart and feet touching in the midline with buttocks at the end of the table (Fig. 158-2). Alternatively, the mother may assist with the frog-leg position (Fig. 158-3). Older children may be placed in adjustable stirrups (Fig. 158-4).
  - Inspect the vulva and areas lateral to it. Use the colposcope or a hand lens with adequate lighting to best visualize the introitus.
  - Gently open the labia by applying gentle lateral and posterior traction just lateral to the vulva at the level of the posterior

**Figure 158-3** Frog-leg position with mother's assistance. (Modified from Khan JA, Emans SJ: Gynecologic management of rape in adolescent girls. Patient Care 33:71, 1999.)

- introitus. Do not force the labia open; they will usually open with persistent gentle traction or the child may assist by holding her labia apart.
- Examine carefully the entire circumference of the introitus and hymen. Normal hymenal variants are illustrated in Figure 158-5. Look carefully for asymmetry, for notching in the posterior hymen, and for posterior hymenal attenuation (thinning; Fig. 158-6). These findings are usually caused by sexual abuse, and rarely by accidental trauma. The significance of the diameter of the hymenal orifice is controversial; do not worry about measurements. If the hymen cannot be fully visualized, ask the child to cough or take a deep breath. Pull the labia gently forward and down or laterally. A colposcope is helpful at this stage. A hand lens can also be used if an assistant can help with the examination.
- Acute trauma from sexual abuse is evidenced by the presence of hematomas, abrasions, lacerations, hymenal transections, or vulvar erythema. These conditions usually resolve within 10 to 14 days.
- Cultures can be taken at this time (assuming the child is comfortable) or after the knee-chest examination.
- 4. Knee-chest examination (for children older than 2 years)
  - Most young children readily adopt this position with a little encouragement. Buttocks should be higher than the back, with knees approximately 25 cm (12 inches) apart. The child can rest her head to one side on her folded arms or pillow (Fig. 158-7).
  - Gentle traction laterally will often open up the labia. Ask the
    patient to take 10 slow, deep breaths because this will also
    relax the perineal structures.
  - Use the colposcope (or hand lens with an assistant) to look at the posterior hymen. The knee-chest position is the preferred position for detecting small but significant abnormalities of the hymen. Again, look for asymmetries, notching, or attenuation. Take photographs or carefully document if abnormalities are seen.
  - The lower vagina may be visualized in this position, and the upper vagina and cervix in 80% to 90% of prepubertal girls. Also, examine the rectum in this position.
- 5. Resume the frog-leg position if cultures are needed. Perform the following only if vaginal discharge or pain is noted, if there is genital itching or odor or urinary symptoms, or if there are genital ulcers or lesions. Consider cultures if the prevalence of STIs in the community is high, if a sibling or another child or adult in the household has an STI, or a known assailant has an STI or is at high risk.
  - Culture for Chlamydia. Collect the specimen as deeply in the posterior vagina as you can. Use a cotton or calcium alginate swab. If possible, it should be moistened with nonbacterio-static saline to minimize the discomfort. Before inserting, allow the child to feel a similar swab on her skin. Avoid touching the hymen when obtaining the culture. It may also be helpful to ask the child to cough in order to distract her and open the hymen. A male urethral swab may also be used to gently scrape the vaginal wall.
  - Alternatively, a vaginal wash and aspiration can be obtained. Using a small feeding tube attached to a small syringe, insert the tube into the vagina and inject and aspirate 0.5 to 1 mL of sterile saline. A soft plastic or glass eyedropper with 4 to 5 cm of intravenous plastic tubing attached can also be used in the same manner. Insert the catheter into the vagina and inject and then aspirate the saline.
  - For gonorrhea (gonococci), use a cotton or calcium alginate swab to obtain samples from the following: throat, deep in the posterior vagina, and rectum. Place them on a single plate partitioned into thirds (this is done to reduce the number of cultures needed). If any area of the plate is actually positive, you will need to reculture each area separately to confirm the

**Figure 158-4** Lithotomy position with use of stirrups. (Modified from Khan JA, Emans SJ: Gynecologic management of rape in adolescent girls. Patient Care 33:71, 1999.)

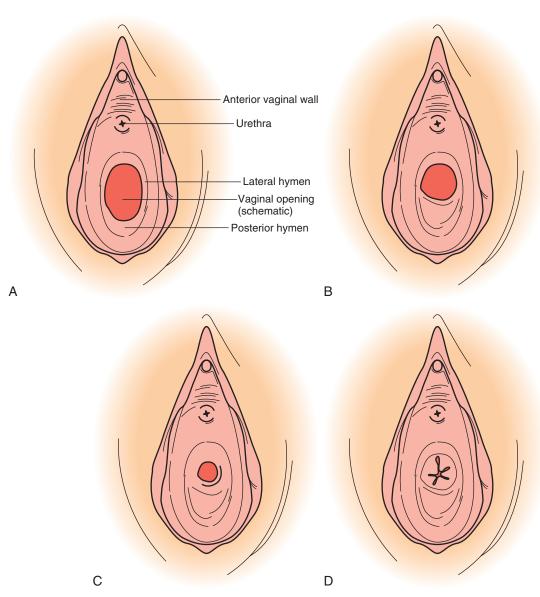

Figure 158-5 Variants of normal hymen. **A,** Normal hymen. **B,** Posterior rim or crescentic hymen. **C,** Circumferential or annular hymen. **D,** Fimbriated or redundant hymen. (Modified from Khan JA, Emans SJ: Gynecologic management of rape in adolescent girls. Patient Care 33:71, 1999.)

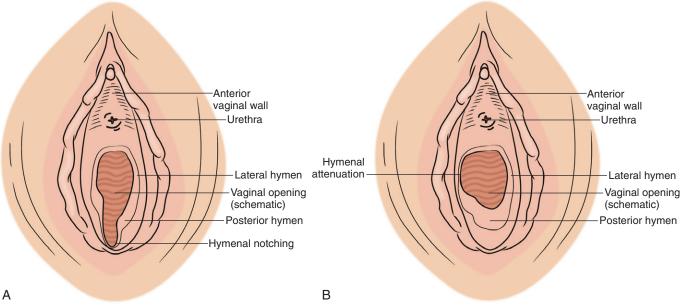

Figure 158-6 A, Hymenal notching. B, Hymenal attenuation.

location. A false-positive chlamydial or gonococcal culture is very rare, so it should be investigated.

- Obtain a herpes culture if it is suspected.
- Cultures for other organisms can be obtained by placing the calcium alginate swab into a transport Culturette II (contains medium) or by sending the aspirated fluid to your local hospital laboratory for direct plating.
- Obtain a wet prep or KOH prep if indicated.
- Note and document the presence of any condylomata.

**NOTE:** Cultures are the standard for forensic evidence. DNA probe specimens may, however, be helpful in some instances as an adjunct to cultures.

6. In addition to the aforementioned studies, consider a urine culture, syphilis serology, and hepatitis B and human immunodeficiency virus testing on all patients because of the paucity of clinical findings with these diseases. Parents may also be reassured by doing these studies.

NOTE: Foreign bodies are often found as the cause of a discharge. Removal may be possible with a cotton-tipped applicator or by

Figure 158-7 Knee-chest position. (Modified from Khan JA, Emans SJ: Gynecologic management of rape in adolescent girls. Patient Care 33:71, 1999.)

lavaging the vagina with saline or warm water. Viscous lidocaine may be useful for anesthesia at the introitus.

- 7. Send all cultures to the laboratory, using *chain of evidence* form and precautions (Fig. 158-8).
- 8. After the examination, congratulate the child for her cooperation. Discuss the results and the diagnosis and management plan with the child and her parent(s) after she is dressed. Because the results of the examination are often inconclusive, help the parent(s) to understand that a careful and complete investigation includes protective services or law enforcement officials, or both.
- Implications of positive laboratory findings are set out in Table 158-1. Table 158-2 contains guidelines for making reporting decisions.

## **Uncooperative Patients**

The uncooperative patient calls for patience and artistry on the part of the examiner. Often (but not always), proceeding through the examination slowly will result in a satisfactory examination. Leaving the room and returning when she is ready often allows a child to regain control.

Nasally administered midazolam (Versed), a short-acting benzodiazepine (dosage 0.2 to 0.4 mg/kg of the *injectable* solution) can enhance cooperativeness. When administered by this route (use a tuberculin syringe without a needle), the drug will be effective within 15 minutes. Side effects are rare. Versed syrup is available as another option, but therapeutic onset is longer. The child must be observed by a knowledgeable parent or by your staff for about 1 to 2 hours after the drug is given. This anxiolytic technique requires no intensive monitoring (see Chapter 7, Pediatric Sedation and Analgesia).

Antibiotics are rarely indicated. Usually, the alleged abuse occurred long ago.

## **PATIENT EDUCATION GUIDES**

See the patient education form available online at www. expertconsult.com. To find a regional child advocacy center, consult the National Children's Alliance website at www.nca-online.org.

### **Chain of Evidence Form**

- \* PLEASE COMPLETE CAREFULLY—THIS FORM IS REQUIRED FOR LEGAL PURPOSES
- 1. Use this LOG to document specimen transfer so that "chain of evidence" can be preserved.
- 2. Each time the specimen changes hands, the new carrier-technologist must place his or her initials on the form in the appropriate location and must mark the date and time.
- 3. When the final laboratory report is prepared, staple securely to the LOG before sending the report to the ordering clinician.
- 4. Please use separate forms if specimens of different types are submitted (e.g., blood specimen and GC culture) or if specimens are sent to different labs.
- 5. If you perform the laboratory test in your office, have each staff member who handles the specimen initial the form. Anyone in attendance during the history and examination should sign as a witness at the bottom of the form.
- 6. If you have questions, call the ordering clinician.

Patient's name:	Patient's name: Date:

# **VULVAR BIOPSY**

Gregory L. Brotzman

Evaluation of the vulva is an important component of a routine gynecologic examination. Although most lesions found are benign, such as skin tags, condylomata, and simple nevi, biopsy is occasionally needed to obtain a clearer understanding of the lesion present. This is especially true in older women and in those who smoke, because they have a significantly increased risk of developing vulvar intraepithelial neoplasia (VIN) or cancer.

Depth of biopsy is an important consideration. Disease of the *non-hair-bearing areas* of the vulva (labia minora, fourchette, interior aspect of the labia majora) is usually only 1 to 2 mm in depth. In contrast, *hair-bearing areas* (outer aspect of labia majora) may have disease that follows the hair shaft and may be several millimeters in depth. Deep biopsies are not necessary for non-hair-bearing vulvar skin areas, but biopsies should go down full depth to adipose tissue where hair is present. An elevated lesion can be shaved off (see Chapter 32, Skin Biopsy) if it is certain not to be a melanoma (e.g., seborrheic keratosis, condyloma, or benign nevus).

Examination of the vulva is aided by the use of a colposcope (low-power setting, 5×) or a magnifying glass after soaking the skin with 3% to 5% acetic acid (vinegar) using a spray bottle or large cotton applicators. Use of vinegar helps delineate dysplastic tissue and warty changes by turning them white (acetowhite epithelium).

Vulvar biopsy is a straightforward, easy-to-perform office skill that allows the practitioner to differentiate benign from neoplastic lesions, often being curative when the entire lesion is encompassed by the biopsy.

In addition to this chapter, see Chapters 22 to 25 on excision of lesions and follow-up repair; Chapter 32, Skin Biopsy; and Chapter 155, Treatment of Noncervical Condylomata Acuminata.

## **ANATOMY**

Figure 159-1 shows basic vulvar anatomy as well as the orientation of lines of skin tension. Skin tension lines are important in considering excisional or punch biopsies of the vulva. With the index finger and thumb of the nondominant hand, the skin should be stretched in the opposite direction of (perpendicular to) the tension lines, so that the excision margins form an ellipse after release. This allows an easier closure if sutures are used.

## **INDICATIONS**

- Pigmented lesions
- Vulvar ulceration of uncertain etiology or a nonhealing ulcer
- White epithelium (skin that turns white after the application of 5% acetic acid)
- Leukoplakia (white skin before the application of acetic acid)
- Presumed condylomata that do not readily respond to conventional therapy (if not resolved or significantly improving after two treatment attempts of any kind)
- Any skin abnormality that needs definitive diagnosis

### **CONTRAINDICATIONS**

#### **Absolute**

An allergy to local anesthetic/preservatives is the only absolute contraindication.

#### Relative

- Bleeding diathesis
- Recent (<3 weeks) chemical destruction attempts. These may result in false-positive histologic findings owing to reparative changes. It is best to wait until healing has occurred after any treatment before attempting a biopsy of such lesions.

#### **EOUIPMENT**

- 3-mm Keyes punch biopsy (4 and 5 mm also acceptable but may require suturing, whereas 3 mm does not; Fig. 159-2A), a cervical punch biopsy forceps (Fig. 159-2B), or sharp tissue scissors (Fig. 159-2C) or a no. 15 blade for elevated or non-hair-bearing areas ("shave biopsy")
- No. 15 scalpel blade for excision
- 1% lidocaine (Xylocaine) with or without epinephrine (can mix 1:10 with sodium bicarbonate solution to decrease discomfort)
- 30-gauge, ½-inch needles
- 1- to 5-mL syringe
- Nonsterile gloves (sterile gloves needed if placing sutures)
- Formalin containers
- Iris scissors (see Fig. 159-2C)
- Pickups (Fig. 159-2D)
- Povidone–iodine or alcohol swabs
- Monsel's solution (thickened ferric subsulfate solution) or aluminum chloride solution (Drysol)
- Small cotton-tipped applicators
- Antibiotic ointment
- 3 mm disposable (sharp) dermal curette

## PREPROCEDURE PATIENT EDUCATION

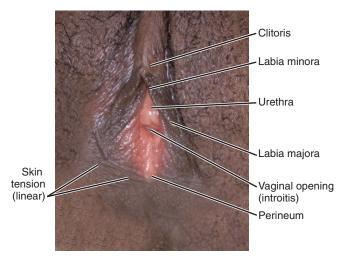

If there are no contraindications, have the patient take 600 mg of ibuprofen 1 hour before the procedure to help with postprocedure discomfort.

### **PROCEDURE**

There are four ways to perform a biopsy of the vulva:

- 1. Punch biopsy (with a Keyes punch or cervical biopsy forceps)
- 2. Excisional biopsy (using a no. 15 scalpel blade)
- 3. Shave excision (using tissue scissors or a blade)
- 4. Curettement using a 3-mm disposable (sharp) dermal curette

Deciding which type of biopsy technique to use depends on the size and location of the lesion (see earlier discussion). A large or

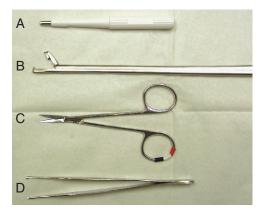

**Figure 159-1** Vulvar anatomy. The vertical and horizontal lines demonstrate the lines of skin tension. When a biopsy is being performed, stretch the skin in the direction opposite to the skin tension lines so that after the biopsy is done, the skin will form an ellipse when relaxed, making it easier to close if sutures are needed.

deep lesion would likely require punch biopsies to sample it, or it may be possible to excise it in its entirety with an excisional biopsy technique. Frequently, small lesions can be excised completely with a punch or shave biopsy. Most punch biopsies do not require suturing, whereas excisional biopsies do. The curette technique can be used to sample a large lesion or to remove small, especially papular, lesions.

# **General Technique**

- 1. Draw up 1 to 5 mL lidocaine with or without epinephrine, mixed with a 10:1 ratio of lidocaine to bicarbonate solution, 1 mEq/mL (avoid use of epinephrine around the clitoral area). One may also use a small amount of a topical anesthetic such as 5% lidocaine cream (LMX5) applied with a cotton-tipped applicator to the area to be sampled. This is left on for 5 minutes before local anesthetic infiltration.
- 2. Identify the lesion.
- 3. Prepare the skin with a povidone-iodine swab or alcohol.
- 4. Inject around and under lesion with local anesthetic to raise the lesion (Fig. 159-3A).
- 5. Test skin with needle to be sure anesthesia is adequate (should be immediately effective).

**Figure 159-2 A**, Keyes punch biopsy. **B**, Cervical punch biopsy forceps. **C**, Iris scissors. **D**, Tissue forceps.

- 6. Stretch the skin in direction opposite of skin tension lines in the vulvar area (i.e., stretch horizontally for a labial biopsy and stretch vertically for a perineal biopsy).
- 7. If using a blade, curette, or scissors to remove lesion, stay more superficial in non–hair-bearing areas.

## Technique for a Keyes Punch

- 1. To obtain deeper samples (e.g., hair-bearing areas), place punch over lesion perpendicular to the surface and slowly twist with minimal pressure on the punch instrument (let the cutting occur with the instrument; Fig. 159-3B).
- 2. Continue until you feel a "give" and the punch is loose from the surrounding tissues.
- Gently grasp the edge of the lesion or the subcutaneous portion of the biopsy with the tissue forceps and lift up (avoid grasping the central portion of the lesion because this may cause crush artifact to the specimen).
- 4. Snip the base of the specimen with iris scissors and remove the biopsy sample (if multiple biopsies of the same lesion are obtained, each sample should be placed in its own container; Fig. 159-3C).
- Apply a small amount of Monsel's solution or aluminum chloride solution to the biopsy crater, using a small cotton-tipped applicator.
- More resistant bleeding may be treated with a small piece of Gelfoam, electrocautery, or an absorbable suture.
- Wipe away any excess hemostatic agent or blood with salinemoistened gauze.

**NOTE:** After either a punch biopsy or an excisional biopsy, apply a small amount of antibacterial ointment to the biopsy site.

# **Technique for Using Cervical Punch Biopsy Forceps**

- 1. Place the forceps jaws perpendicular to the surface of the lesion and grasp the skin. This will cause tenting of the skin (Fig. 159-3D)
- Close the biopsy forceps to obtain the biopsy. The goal is to obtain approximately a 3-mm-wide and -deep biopsy.
- Apply a small amount of Monsel's solution or aluminum chloride solution to the biopsy crater, using a small cotton-tipped applicator.
- Wipe away any excess hemostatic agent or blood with salinemoistened gauze.

### Technique for an Excisional Biopsy

Figure 159-4 illustrates an excisional biopsy. See Chapter 32, Skin Biopsy, for further details on performing an excisional biopsy with repair.

## **COMMON ERRORS**

- Not sampling the most advanced part of the lesion. If uncertain, take multiple biopsies for large lesions. An area that is more darkly pigmented and raised, or an area of leukoplakia, is usually more advanced.
- Taking too deep of a sample. Use careful technique to take only the depth of specimen necessary.

## **COMPLICATIONS**

The following complications are extremely rare:

- Infection
- Bleeding, hematoma, ecchymosis

Figure 159-3 Example of punch biopsy. **A,** The lesion is anesthetized. **B,** Biopsy is performed with a Keyes punch. **C,** If a Keyes punch is used, once the skin is free from surrounding tissues, snip base with iris scissors. **D,** Alternatively, biopsy is performed with a cervical biopsy forceps. (**B** and **D,** Courtesy of Hope Haefner, MD.)

- Hypopigmentation
- Pain
- Scar
- Recurrence
- Hyperpigmentation from Monsel's solution (usually temporary)

# **POSTPROCEDURE PATIENT EDUCATION**

Instruct the patient to perform the following after the procedure:

- Wash the area twice a day with soap and water.
- Apply antibiotic ointment after each cleansing.
- Use acetaminophen or ibuprofen for discomfort (first determine any contraindications to the use of these medications in the patient).
- Take sitz baths as needed for discomfort if extensive removals are performed.
- Use ice packs as needed.
- For more recalcitrant pain, use over-the-counter benzocaine gel (toothache-type pain reliever) as needed.
- Call if there is persistent pain, redness, or swelling.
- Avoid intercourse until discomfort is gone (usually 3 to 5 days).
- Arrange a follow-up appointment or phone call to discuss biopsy results.

## **PATIENT EDUCATION GUIDES**

See patient education and patient consent forms available online at www.expertconsult.com.

## **CPT/BILLING CODES**

56501 Destruction benign lesion vulva, single

56515 Destruction benign lesion vulva, extensive

56605 Biopsy of vulva or perineum (one lesion)

56606 Biopsy of each additional vulvar or perineal lesion

# WET SMEAR AND KOH PREPARATION

Gary R. Newkirk

Abnormal vaginal discharge is a common complaint. In fact, vaginitis is the most common gynecologic diagnosis in primary care. Vulvovaginal candidiasis (VVC), bacterial vaginosis (BV), and trichomoniasis (trich) account for over 90% of abnormal vulvovaginal symptoms and discharge. Frequently, several pathogens may coexist. Office-based wet smear, potassium hydroxide (KOH) preparation, and vaginal secretion pH should be used to ensure a more accurate diagnosis and effective treatment of vaginitis. Empiric treatment for vulvovaginal symptoms including vaginal discharge should be avoided until appropriate testing is performed making a specific diagnosis.

## **ANATOMY**

Obtaining vaginal or vulvar samples to determine the cause of vulvovaginal symptoms and discharge requires familiarization with lower female genital anatomy and the basic skills of pelvic examination. Chapter 137, Colposcopic Examination, and Chapter 151, Pap Smear and Related Techniques for Cervical Cancer Screening, review the anatomy and basic steps of the pelvic examination.

#### **INDICATIONS**

- Abnormal vaginal discharge
- Vulvar or vaginal itching, burning, or pain
- Discomfort with intercourse

# **CONTRAINDICTIONS**

- Active menses (clinician should not postpone evaluation for significant discharge or vulvovaginitis during menses)
- Recent douching (relative contraindication)
- Recent application of vaginal creams or lubricants (relative contraindication)

## **EQUIPMENT AND SUPPLIES**

- Vaginal speculum
- Small cotton-tipped applicators
- Small test tubes
- Normal saline
- 10% potassium hydroxide solution
- Glass slides and coverslips
- pH test tape (narrow range needed: Micro Essential laboratory; pH paper on a stick: Imagyn Gynecology)
- Microscope

### **PRECAUTIONS**

In some instances, women with extremely inflamed vulvovaginitis cannot tolerate speculum insertion. The clinician should be prepared to perform a limited examination by obtaining samples from the distal vagina or vulva.

 The clinician should maintain a high index of suspicion for a primary cervical infection with either Chlamydia trachomatis or Neisseria gonorrhoeae in patients at risk or for those who have an observed mucopurulent cervicitis.

### PREPROCEDURE PATIENT PREPARATION

- Discuss the need for pelvic (speculum) examination and testing requirements that may incur additional costs.
- Written consent is not required, although women should be informed if testing for gonorrhea or *Chlamydia* is performed.
- Educate women during annual pelvic examinations regarding avoidance of douching, creams, and lubricants prior to the evaluation of abnormal discharge.

#### **PROCEDURE**

- With the patient in the lithotomy position begin with careful examination of the vulva for inflammation, ulcers, lesions, and discharge.
- 2. Insert a warm lubricated speculum and expose the cervix.
- 3. Inspect the cervix, vaginal walls, and fornices. Perform cervical sampling for gonorrhea, *Chlamydia*, or herpes as deemed appropriate. Consult with your laboratory on the detection methodology (culture, DNA testing) and technique for sample collection, preparation, and transport.
- 4. Collect secretions from both the vaginal fornices and lateral vaginal walls by gently rubbing with a cotton-tipped applicator. Place the cotton-tipped applicator with sample in a patient identified small test tube that contains 1 mL of 0.9% (normal) saline. Leave the applicator in the test tube until the wet smear is performed in the laboratory. Remove the speculum from the vagina.
- 5. To properly prepare the slide for review, vigorously mix the swab in the saline solution. Remove the swab from the tube and depress it on the slide to express a small amount of fluid. Apply a coverslip over the sample. The slide ("wet prep" or "wet smear") is then immediately examined with the microscope under low power (10×) for vaginal squamous cells, white blood cells, lactobacilli, clue cells, and trichomonads. Examine under low and high power (40×). If a KOH slide is needed, prepare another slide exactly as previously described. Before placing the coverslip, put one drop of a 10% KOH solution on the sample. Apply a coverslip. Allow to air- or flame-dry and examine under low power for hyphae, mycelial tangles, or spores. The "whiff test" is performed when KOH is applied to the sample (see later discussion).
- 6. A pH test of vaginal secretions can improve diagnostic specificity. A vaginal secretion pH of 3.8 to 4.5 is considered normal in premenopausal women. A piece of the pH test tape may be directly applied to the moist vaginal wall or to the vaginal secretions adhering to the speculum when it is removed from the vagina. Standard nitrazine paper is not accurate and narrower pH range test method should be used (narrow range test paper: Micro Essential Laboratory; pH paper on a stick: Imagyn Medical

Technologies, Inc.). Cervical mucus, semen, douche solutions, and blood are alkaline and can interfere with pH testing.

7. Cultures of vaginal secretions can be obtained for *Candida* and non-*Candida* yeast, aerobic vaginitis, or trichomonas. DNA testing is available for candidiasis or trichomoniasis. Cultures are recommended when microscopy and pH testing fail to document a cause for recurrent vaginitis.

## **COMMON ERRORS**

- Not obtaining cervical cultures for gonorrhea, Chlamydia, or herpes in settings where this may be probable. These infections often cause vaginal discharge as well.
- Not obtaining samples from the vaginal wall as well as the cervical fornices.
- Not performing a careful history of patient-directed treatment, such as douching or over-the-counter treatments that can interfere with testing, prior to examination.
- Failure to consider the contribution of chronic douching, spermicidal compounds, or condom-related latex allergy as contributors of vaginal irritation and discharge.

### **COMPLICATIONS**

The most common complication is allowing confusing or conflicting results to lead to misguided or "shotgun" treatment.

## POSTPROCEDURE MANAGEMENT

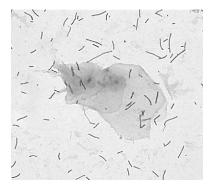

- Offer general education regarding the relationship of vulvovaginitis to self-treatment, douching, use of female "deodorant" or cleansing, latex, or spermicidal products.
- Offer specific instructions regarding the treatment modalities recommended such as intravaginal creams with applicator, oral medications, and side effects (e.g., metronidazole for BV).

### **Interpretation of Results**

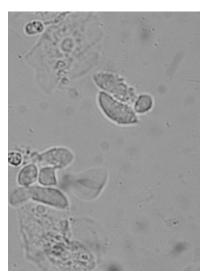

At least five different microscopic fields should be surveyed to observe an adequate number of representative fields. Initially low  $(10\times)$  and high  $(40\times)$  power should be used.

# Findings: Saline Examination ("Wet Prep" or "Wet Smear")

• Lactobacillus species are normal vaginal flora. Lactobacilli are large, long bacillary rods. Their absence or decrease, coupled with an abundance of clue cells and a vaginal pH greater than 4.7, may be consistent with the clinical findings observed in bacterial vaginosis (Fig. 160-1).

**Figure 160-1** Lactobacillus species. (From Morse SA, Moreland A, Holmes K: Atlas of Sexually Transmitted Diseases and AIDS, 2nd ed. London, Gower Medical, 1996.)

**Figure 160-2** Microscopic examination of a wet mount reveals multiple motile trichomonads. (From Zitelli BJ, Davis HW: Atlas of Pediatric Physical Diagnosis, 4th ed. St Louis, Mosby, 2002.)

- Leukocytes at a concentration of more than 5 to 10 cells per high power field (HPF) may indicate infection. If the number of leukocytes exceeds the number of squamous cells, an inflammatory process should be suspected.
- Parabasal cells may indicate low estrogenic state.
- Trichomonads (*Trichomonas vaginalis*) distinctively appear as actively motile protozoans with whipping flagella (Fig. 160-2).
- Clue cells are epithelial cells with indistinct borders often described as "fuzzy" or "dirty" caused by abundant adherent multiple coccobacilli organisms. Clue cells are indicative of bacterial vaginosis (see Figs. 160-1 and 160-2).

### **Findings: KOH Examination**

Hyphae or buds suggest candidiasis (Figs. 160-3 and 160-4). The absence of hyphae but presence of budding spores suggests infection with a non-albicans type of Candida, such as C. glabrata (Fig. 160-5).

## pH Test

The range of values will be determined by the color of the tape.

Normal flora pH 4.5 Candidiasis pH 3.8 to 4.5 Bacterial vaginosis pH 4.7 Trichomonas pH above 4.5

NOTE: Combined infections such as yeast and BV can produce variable pH results.

**Figure 160-3** Low power of KOH preparation, which shows the ghost-like appearance of disintegrating epithelial cells from the KOH and the fungal mycelia and spore forms becoming evident. (Courtesy of Gary R. Newkirk, MD.)

**Figure 160-4** Higher power (40×) of mycelia, budding yeast, and spores supporting the diagnosis of yeast vaginitis. (Courtesy of Gary R. Newkirk, MD.)

**Figure 160-5** High power of KOH preparation with predominately spore forms suggesting Candida glabrata yeast vaginitis. (Courtesy of Gary R. Newkirk, MD.)

## Whiff Test

The presence of a strong amine or "fishy" odor after application of 10% KOH implicates BV. A positive whiff test was predictive of positive culture results for anaerobic flora such as *Bacteroides* species with 67% sensitivity, 94% specificity, and a positive predictive value of 95%.

## **CPT/BILLING CODES**

58999 Unlisted procedure, female genital system (wet smear and KOH preparation)

87220 Tissue examination by KOH slide from skin, hair, or nails

#### **ICD-9-CM DIAGNOSTIC CODES**

112.1 Monilial vulvovaginitis (candidiasis)

131.01 Trichomonal vaginitis

616.10 Vaginitis and vulvovaginitis, unspecified (includes bacterial vaginosis)

623.5 Vaginal discharge

625.9 Unspecified symptom associated with female genital organs

627.3 Atrophic vaginitis

# **AMNIOCENTESIS**

Dale A. Patterson • John J. Andazola

Amniocentesis is very helpful for evaluating an inaccessible in utero patient. Although genetic studies were first performed on amniotic fluid in the 1950s, before the 1970s the primary indication for amniocentesis was the Rh-immunized patient. Since that time, the indications have expanded to include evaluation of fetal lung maturity, fetal genetics, rupture or infection of the amniotic membranes or fluid, and other factors related to fetal health. In some centers caring for high-risk patients, amniocentesis is a routine procedure in approximately 15% of pregnancies. However, the overall frequency of amniocentesis has decreased every year since 1989—down to 1.7% of pregnancies in 2003. It is important to remember that complications from amniocentesis can be serious and occasionally lethal.

### **INDICATIONS**

# Prenatal Diagnosis (First and Second Trimester)

- Chromosomal studies. This is the most common reason for amniocentesis in the United States. Amniotic fluid contains fetal and amniotic cells. The fetal cells include desquamated squamous cells and cells from the gastrointestinal tract, respiratory tract, and urinary system. Although it requires 2 to 3 weeks for results, culture of these cells allows accurate fetal chromosome analysis for chromosomal, sex-linked, and metabolic disorders. For chromosomal analysis, amniocentesis is usually performed at 15 to 17 weeks, when there are sufficient numbers of desquamated fetal cells to allow successful culture. Although early amniocentesis (i.e., 10 to 14 weeks gestation) can be performed, chorionic villus sampling can also be performed around this time for similar indications. The risks and benefits of these procedures are similar but vary slightly by location and indication. Local availability and standards may influence the choice of procedure. Indications for early amniocentesis include the following:
  - Advanced maternal age (35 years of age or older)
  - Parent who is a carrier of a genetic disease that can be diagnosed by amniocentesis
  - Mother who is a carrier of an X-linked disorder
  - History of a child with a chromosomal disorder, neural tube defect, inherited biochemical disorder, or multiple anomalies
  - Mother with a history of three or more spontaneous abortions

**NOTE:** Some experts recommend that mothers be referred to specialized medical centers that perform 50 or more procedures per year for first-trimester or early second-trimester amniocentesis and genetic studies. Less fluid is available at this stage, and there may be less risk of complications with more operator experience. This is particularly important if the procedure must be performed *through* the placenta. A cell culture is also very fragile, and proper transport and assurance against loss or mix-up are essential. It may be best to perform the study at the institution where the cells will be cultured.

- Abnormal prenatal testing results. Triple screen, quad screen, and combined first-trimester screening are examples of frequently used prenatal tests for birth defects. Careful sonographic fetal evaluation in patients with abnormal prenatal testing results may diagnose (or exclude) an open neural tube defect or Down syndrome. Occasionally, amniocentesis may be required for clarification.
- Evaluation for amnionitis. In a patient with ruptured membranes and clinical signs of amnionitis, Gram's stain and culture of amniotic fluid may be performed before initiation of treatment (i.e., antibiotics and prompt delivery of the infant).

# Evaluating Fetal Health (Late Second or Third Trimester)

Bilirubin levels, measured spectrophotometrically as  $\Delta$ OD450, are no longer the standard of care for following the Rh or other blood group isoimmunized pregnancy. This has been replaced by Doppler ultrasonographic measurement of the peak velocity of systolic blood flow in the middle cerebral artery. The sensitivity and specificity of Doppler ultrasonography have been shown to be superior to those of measurement of the amniotic fluid  $\Delta$ OD450. Doppler ultrasonography is noninvasive and thus does not carry the risk associated with amniocentesis. It is recommended that patients with Rh alloimmunization be referred to a center where Doppler ultrasonography of the middle cerebral artery is performed.

## **Evaluating Fetal Maturity (Third Trimester)**

Another common reason for performing amniocentesis is to assess fetal lung maturity. Lecithin (L), sphingomyelin (S), and phosphatidylglycerol (PG) are phospholipids in the newborn lung that act as surfactants and lower the surface tension in the alveoli. Using amniocentesis to determine the L/S ratio, the presence of PG, or both, may minimize the risk of delivering an infant who will develop respiratory distress syndrome (RDS). Other methods to help determine fetal lung maturity include the foam stability index, fluorescence polarization, and lamellar body counts (Table 161-1). Kits are commercially available to help determine these measurements, or variations on them, and are therefore useful for predicting fetal lung maturity.

## **Therapeutic Interventions**

- Relief of symptomatic polyhydramnios, although this is temporary because the fluid rapidly reaccumulates
- Intrauterine transfusion for Rh-hemolytic disease

### **CONTRAINDICATIONS**

#### **Absolute**

- Infected lesions of the abdominal wall where amniocentesis must be performed
- Patient refusal
- When the results of tests will not change the clinical course

TABLE 161-1	Commonly	y Used Direct	Tests of Fe	tal Lung	<b>Maturity</b>
-------------	----------	---------------	-------------	----------	-----------------

					Predictive e (%)			
		_		Mature	Immature			
Test*	Technique	Time and Ease of Testing <sup>†</sup>	Threshold	Negative Predictive Value	Positive Predictive Value	Blood Contamination Affects Results	Meconium Contamination Affects Results	Vaginal Pool Sample
Fluorescence polarization	Fluorescence polarization with TDx-FLM II	1+	≥55 mg/g of albumin§	96-100	47–61	Yes	Yes	Yes
Lecithin/ sphingomyelin ratio	Thin-layer chromatography	4+	2–3.5	95–100	33–50	Yes	Yes	No
Phosphatidyl- glycerol	Thin-layer chromatography	4+	Present (usually >3% of total phospholipids)	95–100	23–53	No	No	Yes
	Antisera with AminoStat-FLM	l+	0.5 = low positive 2 = high positive	95–100	23–53	No	No	Yes
Lamellar body counts	Counts using commercial hematology counter	2+	30,000–40,000 (still investigational)	97–98	29–35	Yes	No	Not available
Optical density at 650 nm	Spectrophotometric reading	1+	Optical density of ≥0.15	98	13	Not available	Not available	Not available
Foam stability index	Ethanol added to amniotic fluid, solution shaken, presence of stable bubbles at meniscus noted	2+	≥47–48	95	51	Yes	Yes	No

<sup>\*</sup>Commercial versions are available for all tests except optical density and lamellar body counts.

## **Relative**

- Maternal coagulopathy
- Placental abruption
- Problems not diagnosable by evaluation of the amniotic fluid (e.g., teratogen exposure, radiation exposure, drug use early in pregnancy, history of genetic disorders not diagnosable by amniocentesis)

## **EQUIPMENT AND SUPPLIES**

- Real-time diagnostic ultrasonography unit
- Commercial amniocentesis tray or sterile tray containing at least three plain sterile specimen tubes (5 to 10 mL each) with caps; standard-length 20- or 22-gauge spinal needle (no larger than 20 gauge should be used); 20-mL syringe; 5-mL syringe; 1½-inch, 22- or 23-gauge needle; sterile 4 × 4 gauze pads; sterile Band-Aids; and sterile towels for drapes
- Skin antiseptic (e.g., povidone-iodine, chlorhexidine gluconate)
- Fetal heart rate monitor
- Sterile gloves
- Local anesthetic solution (e.g., 1% or 2% lidocaine, without epinephrine) (optional)

**NOTE:** To obtain disposable amniocentesis trays, the clinician should check with a local surgical supplier.

# PREPROCEDURE PATIENT EDUCATION AND FORMS

The clinician should discuss the procedure with the patient (and the patient's partner, if available) beforehand. Both people should be informed of the risks and the benefits of having an amniocentesis. In addition, the clinician should describe alternative modes of evaluation or treatment (if any) and obtain signed informed consent. (See the sample patient education and consent forms available online at www.expertconsult.com.)

## **TECHNIQUE**

- 1. Have the patient lie on the examining table or bed with the head elevated 20 to 30 degrees. Alternatively, perform the procedure with the patient in the slight (15 degrees) left lateral decubitus position. Monitor the fetal heart rate for 20 minutes to establish a baseline.
- 2. Locate a pocket of fluid with real-time ultrasonography (Fig. 161-1). Try to find a pocket that the needle will be able to reach without going through the placenta or near the fetal face. The best locations (associated with low risk of cord puncture) are usually in the area of the fetal extremities. Use the ultrasound *electronic* calipers to measure the depth from the skin that the needle must penetrate to enter the pocket. Note the desired longitudinal angle for the needle. If not perpendicular to the abdomen, note the lateral angle of the probe used to locate the pocket. The needle should be directed at the same lateral angle. Mark the location of the puncture site on the skin using pressure from a needle hub.
- 3. Prepare the abdomen with antiseptic solution.
- 4. The use of local anesthetic is optional. If desired, wearing sterile gloves, raise a skin wheal with the anesthetic at the puncture site, then continue to anesthetize along the course of the needle track to the parietal peritoneum and serosal surface of the uterus (requires 4 to 5 mL of anesthetic solution). Remove the needle.
- 5. With the stylet in place and with concurrent real-time ultrasonographic guidance (transducer in sterile plastic bag, glove, or cover), insert the 20- or 22-gauge spinal needle along the selected track (at the correct angles) to the previously measured depth. The clinician should feel a little "pop" as the needle moves through the fascia. When it penetrates the amniotic membrane, there is sudden free movement.
- 6. Remove the stylet. In most cases the amniotic fluid will flow through the needle. If not, rotate the needle (this may move the tip away from membranes, fetal parts, etc.). If there is no flow of fluid, attach the empty 5-mL anesthetic syringe to the needle hub and apply gentle suction. If there is still no fluid, replace the stylet and advance the needle another 0.5 to 1 cm or until resistance

<sup>†</sup>Range in complexity: 1+ indicates procedure is simple, procedure is available all the time, procedure time is short, and personnel effort is not intensive; 4+ indicates procedure is complex or difficult, time consuming, and, therefore, frequently not available at all times.

<sup>\*</sup>Positive predictive value is the probability of neonatal respiratory distress syndrome when the fetal lung maturity test result is immature.

The manufacturer has reformulated the product and revised the testing procedure. Currently, the threshold for maturity is 55; with the original assay, it was 70.

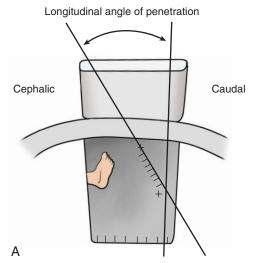

Figure 161-1 Proper insertion of needle. **A,** Graphical depiction. Note measurements with calipers; the needle direction is also determined. **B,** Photograph. Needle is inserted to previously measured depth at the proper angle.

- is felt. Again, remove the stylet. If there is no fluid, reattach the small syringe and withdraw the needle slowly with gentle suction, rotating it as it is withdrawn.
- 7. Once the fluid pocket is located, withdraw 2 or 3 mL of fluid in the small syringe and then discard it. This minimizes the amount of blood in the remaining fluid sample (blood can affect laboratory results). Next, withdraw 15 to 25 mL of fluid (or the volume needed for the tests planned). Remove the needle, clean the excess antiseptic from the abdominal wall, and cover the puncture wound with a Band-Aid. If the patient is unsensitized Rhnegative, administer 300 mg of Rh-immune globulin.
- 8. If no amniotic fluid is obtained, repeat the ultrasonographic examination and again localize the fluid pocket, its angle, and its distance from the skin; prepare the skin with antiseptic and repeat the tap (again under continuous ultrasonographic guidance). It is recommended that no more than two attempts be made because repeated attempts increase the risk of significant fetal injury or induction of labor. It is also important not to use a needle larger than 20 gauge because the incidence of complications rises with needle gauge.

## **SAMPLE OPERATIVE REPORT**

The patient was placed in low semi-Fowler's position and the fetal heart tones were monitored for 20 minutes. Real-time ultrasonography was used to locate a collection of amniotic fluid in the area of the fetal extremities at a depth of 5 cm. No loops of cord were noted. The overlying skin was marked, prepped with povidone—iodine solution, and draped with sterile towels. After local anesthesia with 1% lidocaine (if used), a 20-gauge spinal needle was inserted into the fluid pocket under continuous ultrasound guidance. A total of 15 mL of clear (or "meconium stained," "slightly blood tinged," "grossly bloody") amniotic fluid was removed without (with) difficulty. A sterile dressing was applied to the puncture site, and the fetal heart tones were monitored for another 20 minutes; these remained reassuring. The patient felt well and was discharged with warnings and instructions for follow-up.

#### **COMPLICATIONS**

A wide variety of complications have been reported, including injuries and even fetal death. However, serious complications are uncommon and the procedure is considered relatively safe in experienced hands. Complications from amniocentesis include the following:

- Pain, bruising, or infection at the puncture site
- Abdominal visceral injury

- Uterine contractions, occasionally progressing to labor but usually self-limited
- Occasional (0.8% to 1.1% risk) spontaneous abortion after late first-trimester or midtrimester amniocentesis
- Premature rupture of membranes
- Placental separation or abruption
- Fetal injury, such as skin scars, dimpling, eye injury, genital injury (risk increases with oligohydramnios)
- Orthopedic deformities of the newborn
- Cord or placental blood vessel injury with resultant fetal hemorrhage
- Rh-factor isoimmunization
- Uterine or amniotic fluid infection
- Fluid leak with resultant oligohydramnios (rare)

# POSTPROCEDURE MANAGEMENT

After a normal successful amniocentesis, monitor the fetal heart rate and the mother's response for 20 to 30 minutes, after which the patient may leave. Prolonged monitoring for 1 to 2 hours may be indicated if there are frequent uterine contractions or if the sample was grossly bloody. Often, placental bleeding can be seen on ultrasonography and monitored visually.

## POSTPROCEDURE PATIENT EDUCATION

Printed instructions help patients remember what they are told. The clinician should give the patient an instruction sheet to use after amniocentesis.

## INTERPRETATION OF RESULTS

- 1. PG by itself can be used as an indicator of fetal lung maturity. Blood, meconium, or vaginal secretions (as contaminants) in the amniotic fluid do not affect PG. PG does not appear until 35 weeks' gestation; therefore, although it is not an absolute guarantee, the presence of PG provides considerable reassurance against the occurrence of RDS. Also important, the absence of PG is not necessarily a strong predictor of RDS after delivery. Although commercially available kits can be used to document PG presence rapidly and with considerable accuracy, it still usually takes several hours to obtain the results. That is why L/S studies are usually more convenient and still considered the gold standard for fetal lung maturity.
- 2. At about 33 weeks' gestation, the concentration of L relative to S begins to rise, and both can be measured directly. It has been

frequently reported that the risk of RDS is very slight when the L/S ratio is greater than 2, and there is an increased risk of RDS when the ratio is below 2. It should be noted that with some complications of pregnancy, such as maternal diabetes, RDS may occur despite a mature L/S ratio. As a result, some clinicians require the presence of PG before an elective delivery of a diabetic mother. In addition, the presence of blood has been reported to both increase and decrease the ratio, and the presence of meconium can produce falsely mature results.

3. The "shake test" is a rapid screening test for L/S ratio in which varying dilutions of amniotic fluid are shaken with ethanol. Ethanol is a nonfoaming, competitive surfactant that eliminates the contributions of protein, bile salts, and salts of free fatty acids to the formation of a stable foam. At an ethanol concentration of 47.5%, stable bubbles that foam after shaking are due entirely to lecithin in the amniotic fluid. Positive tests, a complete ring of bubbles at the meniscus with a 1:2 dilution of amniotic fluid, are rarely associated with RDS. The shake test is moderately good, but not excellent, at predicting RDS, and it should therefore be regarded as a screening procedure.

To perform the shake test, the clinician should mix 1 mL of amniotic fluid with 1 mL of 95% ethanol. This vial should be compared with a second vial of 1 mL of amniotic fluid mixed with 0.5 mL of 95% ethanol and 0.5 mL of normal saline. After 30 seconds of vigorous shaking, a ring of bubbles in the second vial indicates an L/S ratio of 2 or greater. Bubbles in the 1:1 mix, but not in the second vial, indicate that the fetus is in a bordering stage of development but not yet mature.

- 4. The foam stability index (FSI) is a commercially available variation of the shake test. The kit has test wells built into it containing predispensed amounts of ethanol. Amniotic fluid (0.5 mL) is added to each well and shaken. A "control" demonstrates an example of the stable foam end point. The FSI is read as the highest reading corresponding to a well in which a ring of stable foam persists. This test appears to be a reliable predictor of fetal lung maturity if the FSI is 47 or higher; however, this test is unreliable if the amniotic fluid is contaminated with blood.
- 5. Although results are not available as rapidly as with the shake test, the fluorescence polarization test, or fetal lung maturity (FLM) assay, usually provides results faster than a PG assay. The FLM assesses overall surfactant activity, using polarized light to quantify the competitive binding of a probe to albumin and surfactant in amniotic fluid. An FLM result greater than 55 mg of surfactant per gram of albumin indicates maturity, from 35 to 55 indicates borderline maturity, and less than 35 indicates immaturity.
- 6. Lamellar counts on the amniotic fluid are also quite reliable if they show fetal lung maturity. They are quick, inexpensive, and readily available anywhere that platelet counts are done. Clinicians experienced with lamellar counts often use them as a quick screen to decide who needs the full L/S or PG evaluation. Values of  $50,000/\mu L$  or greater are consistent with fetal lung maturity.

## **PATIENT EDUCATION GUIDES**

See patient education and consent forms available online at www. expertconsult.com.

## **CPT/BILLING CODES**

The clinician should include a picture of the amniotic fluid pocket from the ultrasonographic examination (when possible; Fig. 161-2) and a procedure note in the documentation.

59000 Amniocentesis, diagnostic

59001 Amniocentesis, therapeutic amniotic fluid reduction (includes ultrasound guidance)

76946 Ultrasonic guidance for amniocentesis, imaging supervision and interpretation

**Figure 161-2** Example of an ultrasonographic image to be photographed for documenting the site chosen for amniocentesis. Note the large pocket of fluid and the absence of the cord. Also note the visualization of the needle.

## **ICD-9-CM DIAGNOSTIC CODES**

These are illustrative codes for conditions commonly associated with amniocentesis. A fifth digit (represented by an asterisk) is used in codes 640 to 648 and 651 to 659. Following are the fifth digits used and the episodes of care they represent:

0 Unspecified

Delivered, with or without mention of antepartum condition

2 Delivered, with mention of postpartum complication

3 Antepartum condition or complication

4 Postpartum condition or complication

642.5\* Severe preeclampsia

644.0\* Threatened premature labor (after 22 weeks)

645.2\* Prolonged pregnancy

646.3\* Habitual aborter

654.2\* Previous cesarean delivery, NOS

655.1\* Chromosomal abnormality in fetus

655.2\* Hereditary disease in family, possibly affecting fetus

655.8\* Other known or suspected fetal abnormality, not elsewhere classified

656.1\* Rh isoimmunization

656.3\* Fetal distress

657.0\* Polyhydramnios

658.1\* Premature rupture of membranes

658.4\* Chorioamnionitis

659.6\* Advanced maternal age, primiparous or multiparous

## **ACKNOWLEDGMENT**

The editors wish to recognize the contributions by Clark B. Smith, MD, to this chapter in the previous two editions of this text.

# CESAREAN SECTION

Lee I. Blecher • Benjamin Mailloux

Cesarean section is the operative delivery of an infant and is usually performed to decrease risk of perinatal morbidity and mortality. The term *cesarean* is considered to have been derived from the Latin verb *caedere*, "to cut." The first reported case series of cesarean sections was published in 1591 by Rouseto and Casparo. In the United States, the rate of cesarean deliveries has been increasing every year since 1996, and in 2005 cesarean sections made up approximately 30% of all deliveries. For many years before 1960, the cesarean rate was closer to 5%.

Among family physicians in the United States, 23% actively perform vaginal deliveries and about 7% perform cesarean deliveries. These family physicians are found in a wide variety of practice settings ranging from urban teaching institutions to isolated rural practices. Several family medicine obstetrics fellowships exist to offer additional training for family physicians to perform cesarean sections.

This chapter discusses one standard technique for performing an uncomplicated low transverse cesarean section. It does not attempt to discuss all of the possible techniques or medical situations in which a cesarean section may be necessary. For a more exhaustive review of how to handle complications or more complex surgical deliveries, references are listed in the bibliography.

## **INDICATIONS**

## **Maternal Indications**

- Repeat cesarean when mother declines or fails a trial of labor
- Repeat cesarean when a trial of labor is not indicated (e.g., prior classical uterine incision)
- Antepartum hemorrhage
- · Obstructive pelvic, vaginal, or vulvar tumors or condylomata
- Cervical cancer
- Severe hypertension or severe preeclampsia
- Contracted pelvis (cephalopelvic disproportion)
- Labor intolerance resulting from medical disease
- Uterine rupture
- Maternal thrombocytopenia
- Active maternal herpes simplex genital infection
- Maternal exhaustion or arrest of labor
- Failed postdates induction
- Placenta previa
- Placental abruption

## **Fetal Indications**

- Malpresentation (e.g., brow or face presentation, transverse or breech lie)
- Failed trial of forceps or vacuum
- Arrest of the active stage, including deep transverse arrest
- Nonreassuring fetal heart rate (e.g., recurrent late decelerations, bradycardia, lack of heart rate variability)
- Fetal anomalies
- Cord prolapse
- Shoulder dystocia

- Very low birth-weight infant (<1500 g)
- Multiple gestation or twins with first being nonvertex
- Perimortem
- Macrosomia (controversial; estimated fetal weight >4500 g or >4000 g in diabetic mother)
- Maternal human immunodeficiency virus infection

## **CONTRAINDICATIONS**

Because cesarean section is considered a life-saving procedure in many instances, there are no absolute contraindications other than patient refusal after the consequences have been explained clearly and accepted by the mother.

## **EQUIPMENT**

- Intravenous antibiotic such as cefoxitin 1 g, or for penicillinallergic patient, clindamycin 600 mg
- Terbutaline
- Standard operating room cesarean section package to include the following:

Quantity Needed	Instrument
2	Babcock clamps (if tubal ligation planned)
6	Allis clamps
4	Pennington clamps (8 inch)
2	Tissue forceps (toothed; 6 and 8 inch)
2	Dressing forceps (smooth; 6 and 8 inch)
4 2 2 2 4 2 2 1	Russian forceps (6 and 8 inch)
4	Sponge forceps
2	Adson forceps with teeth
2	No. 20 blade scalpels
	No. 10 blade scalpel
6	Curved hemostats (5½ inch)
6	Curved Kelly clamps
2 4 2 1	Needle holders
4	Kocher or Ochsner clamps (7½ inch)
2	Army-Navy retractors
	DeLee, Fritsch, or Rochard universal retractor
3	Richardson retractors (small, medium, and large)
1	Bandage scissors (7¼ inch)
1	Metzenbaum scissors (7 inch)
1	Curved Mayo scissors (6½ inch)
1	Suture scissors
1	Straight Mayo scissors (6½ inch)
1	Poole suction tip
1	Yankauer tonsil suction tip
4	Packages of suture (two packages each of 0 chromic and 1-0 Vicryl; 2-0 and 3-0 chromic, optional)
20	Lap sponges
1	Surgical stapler
1	Bovie cautery device

Cervical dilators set

# Box 162-1. Typical Preoperative Orders for Cesarean Section

CBC without diff, urinalysis Type and hold 2 units PRBCs

Foley to gravity

Anesthesia pre-op for epidural, spinal, or general anesthesia

IV lactated Ringer's at 125 mL/hr Prep abdomen per MD preference

## **PRECAUTIONS**

There are several conditions that increase the risks associated with performing a cesarean section that should be known, prepared for, and managed where possible.

- Grand multiparity
- Preterm delivery
- Placenta previa
- Placenta accreta
- Morbid maternal obesity
- Transverse lie
- Maternal coagulopathy
- Large uterine fibroids
- Multiple gestation
- Repeat cesarean on patient with extensive adhesions

## PREPROCEDURE PATIENT EDUCATION

Informed consent should be obtained, the patient's questions should be answered, and a consent form signed. A standard hospital consent form can be used, emphasizing the following risks to the patient and infant undergoing cesarean section:

- Complications due to anesthesia
- Injury to the bladder or ureters
- Injury to the bowel
- Need for hysterectomy
- Hemorrhage requiring transfusion
- Infection
- Injury to the fetus (rare)
- Rupture of the uterus during future labors

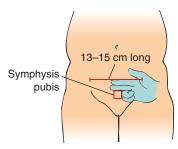

A consent for use of blood products in the event of hemorrhage should also be obtained. Box 162-1 shows typical preoperative orders for a cesarean section.

### **TECHNIQUE**

There are three choices of uterine incision when performing a cesarean section: low transverse (Kerr), low vertical (Krönig), and classic. These are outlined in Table 162-1. The most popular technique, the low transverse (Kerr), is described here.

- 1. Create a left tilt by either tilting the operating table or placing a wedge under the patient when regional anesthesia is used. (This displaces the uterus to the left, which permits better venous return and improves fetal oxygenation.)
- 2. After anesthesia is induced by a regional (epidural), spinal, or general anesthetic, test for anesthesia of the abdominal skin with the Allis clamp.
- 3. When anesthesia is deemed adequate, perform a Pfannenstiel skin incision by incising the abdominal skin to a width of approximately 13 to 15 cm, two fingerbreadths above the symphysis pubis, using a no. 10 blade (Fig. 162-1). Maintain hemostasis from dermal bleeding with Bovie cautery.
- 4. Carry the incision down through the subcutaneous fat to the fascia with the no. 20 blade. In the midline, make a 2-cm horizontal incision in the fascia with the scalpel. Lift the fascia and extend the cut edges laterally and superiorly in a curvilinear fashion with the curved Mayo scissors (Fig. 162-2).
- 5. Grasp the superior edge of the fascia with two Kocher clamps to elevate the fascia off of the underlying muscle, and bluntly dissect the fascia and the heavier fibers of the linea alba away from the muscle with fingers, staying in the midline (Figs. 162-3 and 162-4). This may be more difficult in a repeat case because of adhesive scar formation. In such cases, use the Mayo scissors to cut the adhesions. Then use the Mayo scissors again to cut through the midline fibers of the linea alba. Be careful not to cut the muscle tissue or to cut a "buttonhole" through the fascia. Repeat this dissection on the inferior edge of the fascia, bluntly and sharply dissecting the fascia away from the muscular tissue.
- 6. Bluntly separate the rectus muscle in the midline in a vertical fashion to expose the peritoneum. Grasp the peritoneum superiorly with two hemostats, tent it away from the underlying viscera, and incise with the no. 20 blade (Fig. 162-5). Keep this incision above the urachus (if visualized) to ensure you are above the bladder. Bluntly extend this incision vertically, slightly, being careful not to extend to the bladder inferiorly.
- 7. Place the DeLee bladder blade to retract and identify the bladder.
- 8. Develop the bladder flap (Fig. 162-6) by picking up the peritoneum over the lower uterine segment with tissue forceps and incising it laterally to make a flap approximately 12 cm long

TABLE 162-1	Types of Uterine Incisions	
Incision	Advantages	Disadvantages
Low transverse	Lower uterine segment is thin and less vascular Incision heals well, less risk of subsequent dehiscence Most popular, >90% of all cesarean births	Risk of lateral extension into the uterine vessels
Low vertical	Useful if lower uterine segment is thick or has fibroids For transverse lie with back down For fetal anomalies such as hydrocephalus	Need for greater separation of the bladder from lower uterine segment Need for repeat cesarean section if upper segment entered
Classic incision	Suitable for emergent cases, easiest and fastest access to the infant Better exposure Ability to develop a larger opening for delivery	Increased blood loss Difficult repair (three-layer) Increased risk of rupture in subsequent pregnancies Adhesion formation between incision and abdominal organs Eight times greater risk of dehiscence than transverse incision

**Figure 162-1** Pfannenstiel skin incision. The horizontal incision is carried out two fingerbreadths above the symphysis pubis.

Figure 162-2 Extending the fascia incision using curved Mayo scissors.

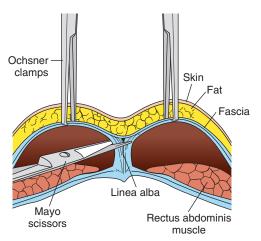

Figure 162-3 Dissection of the linea alba.

**Figure 162-4** Elevating the fascia off the underlying muscle by gripping the superior edge using two Kocher clamps.

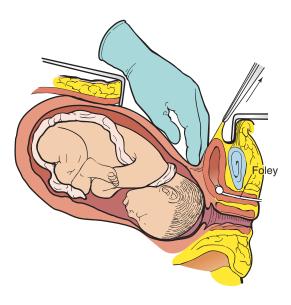

**Figure 162-5** After tenting the exposed peritoneum with two hemostats, a small incision is made before bluntly extending it.

- (Figs. 162-7 and 162-8). Dissect the peritoneum off of the uterus bluntly with the fingers. Reapply the DeLee bladder blade to include the inferior bladder flap just created.
- 9. Determine the position of the lateral uterine vessels as well as the orientation of the uterus. Next, incise the lower uterine segment over the fetal head, known as *scoring the uterus* (Fig. 162-9). Announce "uterine incision" so that the anesthesiologist and nursery attendant can prepare for imminent delivery. It is best to use a no. 20 blade and a 2- to 3-cm incision, proceeding millimeter by millimeter in depth to avoid injuring the presenting fetal part below (Fig. 162-10).
- 10. Extend the uterine incision bluntly with fingers. A bandage scissors may then be used to extend (protecting the fetal parts with two fingers inside the opening) the incision in a superior and lateral direction through the lower uterine segment for a total incision of approximately 10 to 11 cm (Fig. 162-11). However, this carries the added risk of extending the incision into the uterine arteries, so proceed with caution.
- 11. Rupture the membranes with the Allis clamp.
- 12. Deliver the fetal head by inserting a cupped hand over the head and occiput, keeping the wrist straight. Gently lift upward without flexing the wrist, bringing the head out of the incision along with your hand (Fig. 162-12). It may be necessary for the assistant to exert gentle fundal pressure after the occiput has cleared the incision.

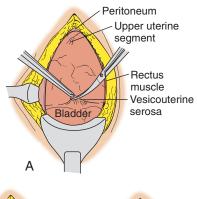

**NOTE:** If the head is flexed tightly or stuck from excessive pushing before the procedure, as is common in arrest of descent cases or true cephalopelvic disproportion, have an assistant push

Figure 162-6 Developing the bladder flap.

**Figure 162-7** Dissection of the bladder away from the uterus.

**Figure 162-8** Development of the bladder flap. **A,** Tenting of the peritoneum. **B,** Undermining the peritoneum. **C,** Incising the peritoneum. (Redrawn from Cunningham FG, MacDonald P, Gant NF, et al [eds]: Williams Obstetrics, 19th ed. Norwalk, Conn, Appleton & Lange, 1993, pp 591–613.)

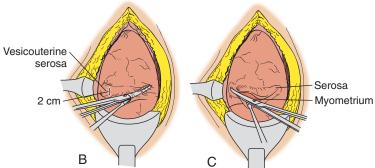

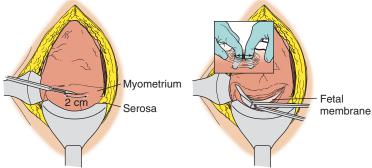

Figure 162-9 Scoring the uterus.

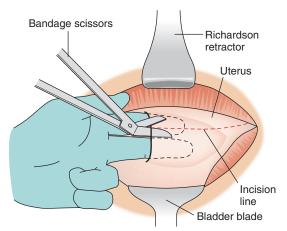

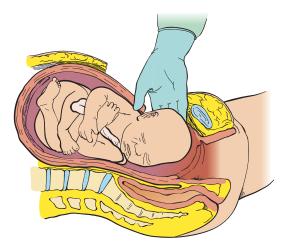

the head inward and upward from below (Fig. 162-13). Occasionally it may be necessary to inject 0.25 mg terbutaline subcutaneously or intravenously (IV) to relax the uterus in order to move the infant upward far enough to allow for delivery. Note that use of terbutaline can increase blood loss from uterine atony.

- 13. Suction the infant's mouth and nose; deliver the anterior shoulder, the posterior shoulder, and then the rest of the infant as in a vaginal delivery. Clamp and cut the cord and hand the infant to the nurse in attendance. Obtain cord blood if necessary, and then manually extract the placenta bluntly with the fingers (Fig. 162-14). Remove the last adherent membranes with the aid of ring forceps.
- 14. Give one dose of perioperative antibiotics after the cord is clamped. This has been proved to reduce postoperative wound infection by 50%. A broad-spectrum cephalosporin, such as cefoxitin 1 g IV, can be used. In penicillin-allergic patients, use clindamycin 600 mg IV in one dose.
- 15. You may choose to externalize the uterus for improved visualization and access, but this is optional. To control blood loss, place two Pennington clamps at the edges of the incision where bleeding is most vigorous. Wrap the uterine fundus in a clean, moist lap sponge as you massage the uterus; gently clean the inner endometrium with moist lap sponges so that it is free of any clots, membranes, and debris. Should the cervix be closed, dilate it with cervical dilators at this point.
- 16. Now close the hysterotomy incision with a running locked stitch of 0 chromic (Figs. 162-15 and 162-16). Should bleeding or oozing continue after a one-layer closure, imbricate with

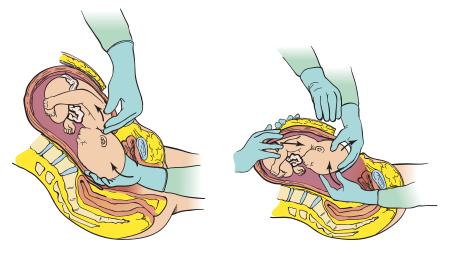

- another layer of 0 chromic. Do not include the endometrial layer in the closure of the myometrium. Should an extension of the incision occur (typically inferiorly toward the cervix), repair the extension first, and then repair the hysterotomy incision. Occasionally, one small area of the hysterotomy incision may bleed and can be repaired with a figure-of-8 stitch for hemostasis.
- 17. Inspect the uterus, tubes, and ovaries. If a bilateral tubal ligation is desired, this is the time to do it.
- 18. Irrigate and suction the pouch of Douglas of clots and debris using warm saline and a tonsil suction tip, and then return the uterus to the abdominal cavity.
- 19. Irrigate and suction the abdominal cavity of clots and debris using warm saline and a tonsil suction tip. Palpate the right and left colic gutters for abnormal structures, and inspect the appendix and gallbladder.
  - Optional: Close the bladder flap/parietal peritoneum with 2-0 chromic. However, most experts do not recommend closing the peritoneum because it will reapproximate on its own without suturing.
- 20. Close the two-layered fascia in a running stitch with 1-0 Vicryl or any other strong monofilament suture. Make sure that the sutures are placed equally across the incision and no more than 1 cm apart (Fig. 162-17).
- 21. Irrigate the subcutaneous fat and stop any bleeding with Bovie cautery (Fig. 162-18).
  - Optional: Close the subcutaneous dead space. This is necessary only for patients with a very large pannus in which it is difficult to reapproximate the skin without this step. Remember that every suture placed is a nidus for possible infection,

**Figure 162-11** Protecting the fetal head from the bandage scissors when incising the uterus. Two fingers are placed under the incision to protect the infant from the bandage scissors.

**Figure 162-12** Lifting the fetal head out of the uterus. Keep the wrist straight to avoid using the uterus as a fulcrum.

**Figure 162-13** Technique to extract an impacted fetal head. An assistant exerts gentle upward force on the head from the vagina as the operator exerts steady upward pressure on the head and shoulders. (Redrawn from Plauché WC, Morrison JC, O'Sullivan MJ [eds]: Surgical Obstetrics. Philadelphia, WB Saunders, 1992, pp 431–436.)

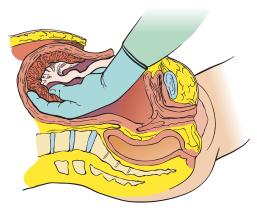

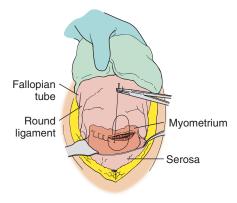

Figure 162-14 Manual extraction of the placenta.

**Figure 162-15** Uterine closure with a running locked stitch of 0 chromic catgut suture. (Redrawn from Cunningham FG, MacDonald P, Gant NF, et al [eds]: Williams Obstetrics, 19th ed. Norwalk, Conn, Appleton & Lange, 1993, pp 591–613.)

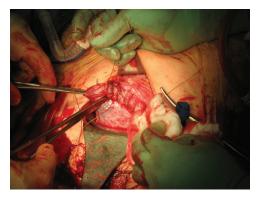

Figure 162-16 Closing the uterus using running locked stitch.

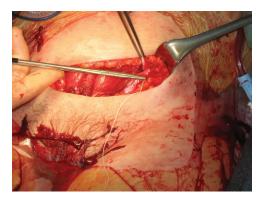

Figure 162-17 Closing the fascia.

Figure 162-18 The subcutaneous fat after closure.

- so keep the amount of suturing to the required steps only. If suturing is required for closure, use interrupted sutures with absorbable suture material, such as 3-0 chromic gut.
- 22. Close the skin. Most surgeons prefer the skin stapler, which does an excellent job when staples are placed 1 cm apart. However, a plastic skin closure with deep buried sutures and a final subcuticular stitch is certainly acceptable if time permits.

#### SAMPLE OPERATIVE REPORT

The sample operative report, available online at www.expertconsult. com, shows an example of an ordinary, uncomplicated case. Any complications should be added and noted in the dictation.

## **COMPLICATIONS**

- From anesthesia
- Injury to the bladder or ureters
- Injury to the bowel
- Uterine hemorrhage
- Infection: endometritis, urinary tract infection, respiratory infection, atelectasis, wound infection, septic pelvic thrombophlebitis
- Pulmonary embolism
- Risk of rupture in future deliveries
- Injury to the child

## **POSTOPERATIVE ORDERS**

Box 162-2 shows typical postoperative orders for cesarean section.

## **POSTPROCEDURE PATIENT EDUCATION**

## First 24 Hours

The patient should be told what to expect, such as pain control issues (e.g., patient-controlled analgesia [PCA] pump versus IV narcotic analgesia). She will experience some uterine cramping and receive fundal massage by the nurses. Her Foley catheter remains in place. She may have the infant with her as early as possible to start breast-feeding and bonding. Most patients stay in the hospital 3 to 5 days after a cesarean section.

## First Postoperative Day

The patient should ambulate to prevent atelectasis and pneumonia. If bowel sounds are present, diet should be advanced to clear liquids and then to full liquids as tolerated. If she is ambulating well, the Foley catheter can be removed and she can walk to the bathroom. The IV line should be changed to a heparin lock. Oral narcotic analgesia can replace a PCA pump, or IV or intramuscular narcotics. She should note some flatus, and urination should increase from postpartum diuresis.

## **Second Postoperative Day**

The criteria for discharge may include a bowel movement, ability to tolerate a regular diet, lack of fever, and full ambulation on oral pain medication only. Many patients can be discharged 36 hours after a cesarean section. *If the skin is closed*, staples can be removed and replaced with Steri-Strips. If not, this can be done at postoperative day 5 on an outpatient basis.

## **Discharge Instructions**

- No driving for 10 days.
- Refrain from intercourse for 4 to 6 weeks.
- Care of the surgical incision is relatively simple. Water can wash
  over the wound as long as there is no direct impact of water onto

# Box 162-2. Typical Postoperative Orders for Cesarean Section

- 1. Admit to the service of
- Admit to recovery room, then to floor as per PACU protocol.
- 3. Monitor vital signs every 15 minutes until stable, then every 30 minutes until anesthesia wears off, then every 4 hours on the floor × 24 hours, then per routine.
- 4. IV lactated Ringer's with 20 units of oxytocin at 125 mL/hr × 1 liter (started in OR).
- 5. After first liter, follow with IV lactated Ringer's at 125 mL/hr.
- 6. Activity: out of bed as tolerated with assistance first time and PRN thereafter.
- 7. Diet: Clear liquids, advance as tolerated.
- 8. Labs: CBC in AM first postpartum day.
- 9. Foley to gravity drainage. Discontinue after 24 hours if urine is clear and patient ambulating.
- Strict intake and output every shift. Discontinue after patient voids at least 250 mL × 2, is tolerating oral intake, and IV fluids are discontinued.
- 11. K-Pad as needed to abdominal incision after 24 hours.
- 12. Call clinician for the following:
  - Temperature over 100.4° F
  - Pulse over 110
  - Increasing uterine tenderness
  - Foul-smelling lochia
  - Excessive vaginal bleeding
- 13. Pain medication
  - PCA pump if available × 24 hours.
  - If not tolerating PO—morphine 2 mg IV q6h PRN.
  - If tolerating PO—Percocet 1–2 tabs PO q4h PRN pain or Dilaudid 2 mg PO q4h PRN pain.
- 14. Other medications to consider
  - Promethazine 6.25–12.5 mg IV q4h PRN nausea.
  - Ondansetron 4 mg IV × 1 PRN nausea.
  - Diphenhydramine 25 mg PO/IV q6h PRN itching or as sleep aid.
  - Simethicone 80 mg 1–2 tablets PO after meals and QHS PRN gas.
  - Bisacodyl 10 mg PR × 1 PRN severe gas/constipation.
  - Methylergonovine 0.2 mg PO/IM q6h PRN excessive vaginal bleeding.
- 15. Breast care and lactation consult PRN.
- Sitz bath 3–4 times daily PRN hemorrhoids and/or perineal discomfort.
- 17. Patient self-administered medications to bedside
  - Sennosides 8.6 mg and docusate 50 mg 2 capsules PO QHS PRN constipation.
  - Perineal spray to perineum PRN pain.
  - Witch hazel pads. Apply 1 pad to perineum/ hemorrhoids PRN discomfort.
  - Anusol-HC ointment to hemorrhoids 3 times daily PRN discomfort.
- 18. Provide RhoGAM if indicated.

the wound. Keeping the wound clean and dry is important for adequate healing. This includes avoiding coverage by skin folds, which can lead to excessive moisture and infection.

- Notify the physician's office for the following problems: pus seeping out of the wound, fever, painful urination, difficulty breathing, shortness of breath, or increasing pain.
- Follow-up in the office for a wound check in 1 week.
- Limit activity to walking for the first week, back to full activity by 6 weeks.

## **CPT/BILLING CODES**

- 59510 Routine obstetric care including antepartum care, cesarean delivery, and postpartum care
- 59514 Cesarean delivery only
- 59515 Cesarean delivery only, including postpartum care
- 59618 Routine obstetric care including antepartum care, cesarean delivery, and postpartum care, following attempted vaginal delivery after previous cesarean delivery
- 59620 Cesarean delivery only, following attempted vaginal delivery after previous cesarean delivery
- 59622 Cesarean delivery only, following attempted vaginal delivery after previous cesarean delivery, including postpartum care

# **ICD-9-CM DIAGNOSTIC CODES**

- 641.01 Placenta previa without hemorrhage, delivered, with or without mention of antepartum complication
- 641.21 Premature separation of placenta (e.g., abruptio placentae), delivered, with or without mention of antepartum complication
- 641.31 Antepartum hemorrhage associated with coagulation defects, delivered, with or without mention of antepartum complication
- 642.51 Severe preeclampsia, delivered, with or without mention of antepartum complication
- 645.11 Prolonged pregnancy, beyond 42 completed weeks of gestation, delivered, with or without mention of antepartum complication
- 647.81 Other viral diseases complicating pregnancy, childbirth, the puerperium, delivered, with or without mention of antepartum complication
- 652.21 Breech presentation, without mention of version, delivered, with or without mention of antepartum complication
- 652.31 Transverse or oblique presentation, delivered, with or without mention of antepartum complication
- 652.41 Face or brow presentation, delivered, with or without mention of antepartum complication
- 652.61 Multiple gestation with malpresentation of one fetus or more, delivered, with or without mention of antepartum complication
- 653.51 Unusually large fetus causing disproportion, delivered, with or without mention of antepartum complication
- 654.21 Previous cesarean delivery, delivered, with or without mention of antepartum complication
- 656.31 Fetal distress, delivered, with or without mention of antepartum complication
- 659.11 Failed medical or unspecified induction, delivered, with or without mention of antepartum complication
- 660.03 Obstructed labor, caused by malposition of fetus at onset of labor, delivered, with or without mention of antepartum complication
- 660.11 Obstructed labor, caused by bony pelvis, delivered, with or without mention of antepartum complication
- 660.31 Obstructed labor, caused by deep transverse arrest and persistent occipitoposterior position, delivered, with or without mention of antepartum complication

- 660.41 Shoulder dystocia, delivered, with or without mention of antepartum complication
- 660.61 Failed trial of labor, unspecified, delivered, with or without mention of antepartum complication
- 660.71 Failed forceps or vacuum extractor, unspecified, delivered, with or without mention of antepartum complication
- 661.01 Abnormality of forces of labor, primary uterine inertia, failure of cervical dilation, primary hypotonic uterine dysfunction, delivered, with or without mention of antepartum complication
- 661.11 Abnormality of forces of labor, secondary uterine inertia, arrested active phase of labor or secondary hypotonic uterine dysfunction, delivered, with or without mention of antepartum complication
- 662.01 Prolonged labor, first stage, delivered, with or without mention of antepartum complication
- 662.21 Prolonged labor, second stage, delivered, with or without mention of antepartum complication
- 663.03 Prolapse of cord, delivered, with or without mention of antepartum complication
- 665.1 Rupture of uterus during labor

# INDUCTION OF LABOR

Scott T. Henderson

Although labor usually begins spontaneously, the induction of labor is one of the most common procedures in obstetrics. It is indicated for both maternal and fetal reasons as well as for elective and social reasons. The frequency at which patients undergo induction of labor has risen from 9% in 1989 to over 20% today. To induce labor, it may also be necessary to manipulate the cervical connective tissue. Therefore, induction can be viewed in two phases, cervical ripening followed by induction of contractions by artificial stimulation of the uterus.

The status of the cervix plays a vital role in the success or failure of an induction. The Bishop Scoring System is a tool that has been used for many years to help quantify the readiness of the cervix for labor (Table 163-1). The maximum score is 13. When the score exceeds 8, the likelihood of a successful vaginal delivery with use of oxytocin approaches that of spontaneous labor. A Bishop score of less than 6 correlates with a prolonged labor or failed induction. For research purposes, there is slight variation in the definition of an unfavorable cervix, with a Bishop score ranging from 4 to 6.

When a cervix is assessed as not favorable, ripening methods should be considered. Historically, nonpharmacologic methods such as breast stimulation, acupuncture, stripping (sweeping) of membranes, and placement of a Foley catheter or laminaria in the cervical os have been used. With the development of artificial prostaglandins (dinoprostone [prostaglandin E2; PGE2] and misoprostol [PGE1]), use of pharmacologic methods has surpassed these other methods. If a cervix is favorable or ripening techniques have been used, it is reasonable to use oxytocin or amniotomy (see Chapter 164, Amniotomy) to stimulate the uterus to have regular and rhythmic contractions.

Providers and nursing staff should develop protocols, as a team, for management of labor induction, including possible complications. These policies should be in written form and followed to maximize safety for the mother and infant and to reduce liability for the providers and institution. Protocols should outline not only the procedural technique but the indications and contraindications. Special attention should be given to the protocols for elective inductions and for induction in women with a previous cesarean section.

## **ANATOMY**

The uterus is normally spontaneously contractile. During gestation, various physiologic mechanisms maintain it in an inactive state. Retention of the fetus is also aided by the cervix, a tight sphincter composed mainly of connective tissue, which maintains the pregnancy's integrity. During the final 4 to 5 weeks of pregnancy, the cervix normally undergoes a "ripening" process. Hormone-mediated changes alter the cervix in both composition and structural organization. It becomes softer and more pliable, and dilates. Endogenous prostaglandins play an important role in this process and also sensitize the uterus to prepare for labor.

## **INDICATIONS**

Induction is indicated when the benefits of delivery to the mother or fetus outweigh the potential risks of continuing the pregnancy. Pregnancy-induced hypertension and prolonged or post-term pregnancies are among the most common indications, accounting for more than 80% of reported inductions. Indications include the following:

- Pregnancy-induced hypertension, preeclampsia, or eclampsia
- Prolonged or post-term pregnancy
- Abruptio placentae
- Abnormal antepartum testing results and delivery indicated
- Chorioamnionitis
- Suspected fetal compromise (e.g., severe fetal growth restriction, isoimmunization)
- Fetal demise
- Premature rupture of membranes
- Maternal medical complications (e.g., diabetes mellitus, renal disease, chronic pulmonary disease, chronic hypertension)

Elective (without medical or obstetric indications) induction of labor is generally not recommended. However, logistic factors such as distance from the hospital, a history of rapid labor and delivery, or psychosocial issues may be reasonable indications for elective induction.

## **CONTRAINDICATIONS**

#### **Absolute**

Absolute contradictions are the same as those for spontaneous labor or delivery, including the following:

- Placenta previa
- Vasa previa
- Transverse fetal lie
- Severe hydrocephalus
- Prolapsed umbilical cord
- Previous classic cesarean incision or other longitudinal uterine scar
- Small maternal size or distorted pelvic anatomy
- Active genital herpes infection
- Invasive cervical carcinoma
- Nonreassuring fetal status
- Known hypersensitivity to prostaglandins (dinoprostone [PGE<sub>2</sub>] or misoprostol [PGE<sub>1</sub>])
- Previous asthma, glaucoma, or myocardial infarction (dinoprostone)

## Relative

- Multiple gestation
- Polyhydramnios

TABLE 163-1 Bisho	p Scoring System				
Assessment Score	Dilation (cm)	Effacement (%)	Station	Consistency	Position of Cervix
0     2   3	Closed I-2 3-4 ≥5	0–30 40–50 60–70 ≥80	-3 (engaged) -2 -1/0 +1/+2	Firm Moderate Soft	Posterior Mid Anterior

Add the score for each of the clinical assessments. If the total score is greater than 8, the success of induction approaches that of spontaneous labor.

- Appreciable macrosomia
- Maternal cardiac disease
- Grand multiparity
- Previous cesarean delivery
- Breech presentation
- Malpresentations
- Presenting part above pelvic inlet
- Unexplained vaginal bleeding during pregnancy
- Prematurity
- Ruptured membranes

# **EQUIPMENT AND SUPPLIES**

- External device for monitoring fetal heart rate (FHR) and uterine activity.
- Sterile gloves.
- Sterile speculum (if membranes ruptured or using dinoprostone gel).
- Intravenous (IV) access (e.g., heparin lock, lactated Ringer's, normal saline).
- Pharmacologic induction supplies: dinoprostone (PGE<sub>2</sub>) gel
   0.5 mg in 2.5 mL (Prepidil) or insert 10 mg (Cervidil); misoprostol (PGE<sub>1</sub>) 100-μg tablet; or oxytocin 10 U/mL (Pitocin).

**NOTE:** Dinoprostone should be stored between  $-20^{\circ}$  C and  $-10^{\circ}$  C. Because misoprostol is available only in a 100- $\mu g$  dosage, it is recommended to have the pharmacist cut the tablet into quarters to ensure the correct dose.

**EDITOR'S NOTE:** A meta-analysis of randomized, controlled trials comparing dinoprostone with misoprostol for cervical ripening and induction of labor found the time to delivery was shorter and the rate of cesarean delivery was lower in the misoprostol group.

- Oxytocin, usually 10,000 to 20,000 mU is diluted in 1 L of lactated Ringer's or normal saline to provide a 10 to 20 mU/mL mixture.
- Infusion pump, if oxytocin is to be used.
- Mechanical induction device (16- to 26-Fr Foley catheter or laminaria [from the brown, cold-water seaweed Laminaria digitata or japonica], available in small, medium, and large sizes) and povidone–iodine solution, sterile 4 × 4 gauze sponges, sponge or uterine packing forceps. One author (Freedman, 2002) suggests use of a blunt-tipped stylet (urologic sound) to help with insertion of the Foley.
- Terbutaline 0.25 mg (at least two doses should be readily available before initiating use of dinoprostone or misoprostol).

### **PRECAUTIONS**

Before proceeding with an elective induction, the provider should review and confirm the dating of pregnancy by at least one of the following:

- 1. Fetal heart tones present for 30 weeks by fetal Doppler or 20 weeks by nonelectronic fetoscope
- 2. Thirty-six weeks since a positive  $\beta$ -human chorionic gonadotropin

- 3. A crown–rump length obtained at 6 to 12 weeks that supports a gestational age of at least 39 weeks
- 4. An ultrasonographic study obtained at 13 to 20 weeks that confirms the gestational age of at least 39 weeks
- 5. Documented fetal lung maturity by amniocentesis (see Chapter 161, Amniocentesis)

Before proceeding with induction in a patient who has had a previous caesarean section, the provider must consider the fact that these patients have an increased rate of uterine rupture, especially those with a failed trial of labor. Although labor induction may be a reasonable option for patients attempting vaginal birth after a cesarean delivery (VBAC), the risk of uterine rupture should be discussed with the patient and documented in the medical record.

**EDITOR'S NOTE:** At many institutions, documented informed consent is required before induction of labor or VBAC.

Caution should be exercised with the use of dinoprostone in patients with ruptured membranes and in patients with a history of previous uterine hypertonia, glaucoma, myocardial infarction, or childhood asthma (even if there have been no asthma attacks in adulthood).

# PREPROCEDURE PATIENT EDUCATION AND FORMS

All patients should be counseled regarding the indications for induction, the expected results, the alternatives, and the possible adverse effects, including the increased risks for cesarean section, uterine hyperstimulation, and fetal distress. The U.S. Food and Drug Administration (FDA) has approved only oxytocin and dinoprostone for labor induction. Review the possible complications with the patient (and family, if present). The clinician should be familiar with the package insert information. With use of prostaglandins, vomiting, diarrhea, or fever may occur, but a recent review of the literature indicated no difference between treatment and control for use of prostaglandins for cervical ripening. Laminaria are made from brown seaweed and act by drawing water from the cervix and swelling, which softens and then dilates the cervix. If a laminaria is inserted, some clinicians will let the patient go home; however, there is a slight increased risk of infection. Anaphylaxis has also been reported. With either laminaria or Foley catheter, the patient will typically experience cramping as the cervix dilates.

Misoprostol is *not* approved by the FDA for this use. There is a "black box warning" against the use of misoprostol during pregnancy. Patients should be informed of the off-label use and possible complications of any prostaglandin, as listed later. It may be helpful to remind the patient that clinicians frequently use medications off-label (e.g., most of the common medications used to halt preterm labor are off-label). Furthermore, misoprostol is contraindicated in patients who have had a previous cesarean delivery.

## **TECHNIQUE**

Before initiating any method of labor induction, the provider should perform a cervical assessment and calculate a Bishop score. In addition, the patient should have a nonstress test (NST) and be assessed

for regular uterine contractions (see Chapter 165, Antepartum Fetal Monitoring). If the NST is nonreactive or a normal uterine contraction pattern is noted, the provider should not proceed with the insertion of any labor induction medication at that time.

#### Mechanical

### Foley Catheter

- 1. Using sterile technique, cut off the tip (the portion beyond the balloon) of the 16- to 26-Fr Foley catheter. After cleansing the cervix with a povidone—iodine soaked gauze sponge or swab, the Foley is introduced into the endocervix by direct visualization. (One author [Freedman, 2002] uses a 16-Fr Foley to ensure adequate diameter for inserting a stylet; this keeps the Foley stiff when inserting. Make sure the stylet does not protrude beyond the tip of catheter, where it might rupture membranes). The Foley is then guided through the endocervix and into the potential space between the amniotic membrane and the lower uterine segment.
- 2. The balloon reservoir is inflated with 30 to 50 mL of normal saline.
- 3. The balloon is then retracted so that it rests on the internal os. The following additional steps may be taken:
- 4. Pressure, either constant or intermittent, may be applied by adding weights to the catheter end. Constant pressure can be achieved by attaching 1 L of IV fluid to the catheter end and suspending it from the end of the bed. Intermittent pressure can be obtained by a gentle tug on the catheter end two to four times per hour.
- 5. Remove the catheter 6 hours later, at the time of spontaneous expulsion, or rupture of membranes (whichever occurs first).

#### Laminaria

- After cleansing the cervix with a povidone-iodine soaked swab, the anterior aspect is grasped with a tenaculum.
- Using a sponge or uterine packing forceps, a laminaria of appropriate size is then inserted so that the tip will rest against the internal os. The laminaria will increase in diameter by three- to fourfold.
- After 4 to 6 hours, remove the laminaria and reevaluate the cervix. If the cervix remains unfavorable, the procedure may be repeated with a second laminaria of larger diameter.

# **Pharmacologic**

## Dinoprostone Gel

- 1. Obtain IV access (optional).
- 2. Connect the appropriate shielded catheter (20 mm in length if no cervical effacement is present or 10 mm if greater than 50% effacement) to the filled syringe.
- 3. For proper gel administration, the patient should be in a dorsal position. To help ensure proper placement of the gel, a speculum can be used to visualize the cervix.
- 4. Under sterile conditions, insert the catheter into the vagina. Use a gentle expulsion technique to express the contents of one syringe (0.5 mg) into the cervical canal just below the level of the internal os (Fig. 163-1). If the tube becomes disconnected, spread the remaining contents of the syringe onto the cervix with your fingers. Use the contents of one syringe for one patient only. After injection, do *not* attempt to administer the small amount of gel remaining in the catheter. Discard the syringe, catheter, and any unused package contents after use.
- 5. The patient should remain supine for at least 15 to 30 minutes to minimize leakage from the cervical canal. Maintain external fetal monitoring of FHR and uterine activity for 2 hours after the installation. Monitoring may be discontinued after 2 hours if there is no uterine activity or FHR abnormality.

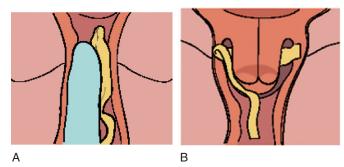

Figure 163-1 Application of dinoprostone (PGE<sub>2</sub>) gel.

- 6. Reevaluate the cervix after 6 hours. If there is minimal change, the procedure may be repeated with a second dose. If needed, a third dose may be administered after 6 more hours. The maximum recommended cumulative dose for a 24-hour period is 1.5 mg of dinoprostone.
- 7. The package insert recommends an interval of 6 to 12 hours between the use of dinoprostone gel and oxytocin. However, some clinicians will initiate oxytocin in 4 hours if there is no uterine hyperactivity.

## Dinoprostone Insert

- 1. Obtain IV access (optional).
- 2. Cervidil is supplied in an individually wrapped aluminum/polyethylene package with a tear mark on one side of the package. The package should be opened only by tearing the aluminum package along the tear mark. The package should *never* be opened with scissors or other sharp objects, which may compromise or cut the knitted polyester pouch that serves as the retrieval system for the polymeric slab.
- 3. On bimanual examination, insert the dinoprostone 10 mg insert and then place it transversely in the posterior fornix of the vagina (Fig. 163-2). A minimal amount of water-soluble lubricant can be used to assist with insertion. The vaginal insert must not be used without its retrieval system.
- 4. The patient should remain supine for at least 2 hours after insertion but thereafter may be ambulatory. Maintain external fetal monitoring for 2 hours after the installation. Monitoring may be discontinued after 2 hours if there is no uterine activity or FHR abnormality.
- 5. The insert should be removed on onset of labor or 12 hours after insertion. Reevaluate the cervix at that time. On removal of the insert, it is essential to confirm that the slab has been removed by visualizing the knitted polyester retrieval system and confirming that it contains the slab. In the rare event that the slab is not contained within the polyester retrieval system, a vaginal examination should be performed to remove the slab and prevent the continuing delivery of the active ingredient.
- The insert should be removed at least 30 minutes before oxytocin administration, if uterine hyperstimulation is encountered, or before amniotomy.

**Figure 163-2** Application of dinoprostone (PGE<sub>2</sub>) insert. **A,** Insertion, **B,** Final placement. (Redrawn from Cervidil insert, Forest Pharmaceuticals, Inc., St. Louis.)

#### Misoprostol

- 1. Obtain IV access (optional).
- 2. On bimanual examination, insert 25  $\mu g$  of misoprostol (one quarter of 100- $\mu g$  tablet) into the vaginal fornix (Fig. 163-3). Certain protocols recommend continuous uterine and fetal monitoring after insertion. At a minimum, maintain external fetal monitoring for 2 hours after the installation.
- 3. Reevaluate the cervix after 4 hours. If there is minimal change, the procedure may be repeated with a second dose.
- 4. Misoprostol should be held if two or more contractions occur in 10 minutes, a Bishop score of 8/13 has been achieved, active labor begins, or the FHR pattern is nonreassuring. Oxytocin should not be administered sooner than 2 hours after the last dose of misoprostol.
- 5. Misoprostol is not recommended for use in this manner for more than 24 hours.

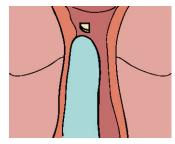

Studies have been done on higher doses and shorter dosing intervals of misoprostol. However, both are associated with a greater incidence of side effects such as hyperstimulation and FHR abnormalities. Studies have also been done on the use of oral misoprostol. It appears that oral misoprostol, 100 mg every 3 to 4 hours, is safe and effective for cervical ripening.

## Oxytocin

Oxytocin is the preferred pharmacologic agent for inducing labor when the cervix is favorable or ripe. It is administered as a dilute IV solution, with the flow rate precisely regulated by an infusion pump. Protocols vary on the number of units of oxytocin per liter of fluid (typically lactated Ringer's or normal saline). Providers can speak with their hospital's pharmacy to determine which concentrations are typically used at their institution.

As with other pharmacologic means of induction, fetal monitoring is indicated before beginning the infusion. Monitoring of FHR and uterine activity should continue throughout the administration of oxytocin. If higher doses are used, strong consideration should be given to the use of an internal fetal monitor and an intrauterine pressure catheter (see Chapter 171, Intrauterine Pressure Catheter Insertion).

Multiple protocols have been established regarding the initial dose of oxytocin and the amount and frequency of dosage increases (Table 163-2). Starting doses typically range from lower doses of 0.5 to 2 mU/min to as much as 6 mU/min. The increment of dosage increase has ranged from as low as 1 to 2 mU/min to as much as 6 mU/min, with adjustments for uterine hyperstimulation. Time intervals between dosage increases in protocols usually range from 15 to 40 minutes. The goal of any protocol is to obtain an adequate labor pattern with contractions 2 to 3 minutes apart, of 45- to 60-second durations, with 50- to 75-mm Hg intensity, and a normal resting tone between contractions. The higher initial doses and more frequent increases in dosing appear to decrease the risk of cesarean section for uterine dystocia, especially for nulliparas. This has resulted in the development of Active Management of Labor

**Figure 163-3** Insertion of  $\frac{1}{4}$  tablet of misoprostol (PGE<sub>1</sub>).

<b>TABLE 163-2</b>	Oxytocin Protocols			
Regimen	Starting Dose (mU/min)	Incremental Increase (mU/min)	Frequency of Increasing Dosage (min)	
Low dose Alternative low dose	0.5–1 1–2	2	30–40 15	
High dose Alternative high dose	6 4	6 (max. 40 mU/ min) 4 (max. 32 mU/ min)	15 15	

protocols that seem to reduce the risk of cesarean section in nulliparas. Regardless of protocol, approximately 90% of patients typically respond to 16 mU/min or less, whereas it is most unusual for a patient to require more than 20 to 40 mU/min to obtain an adequate labor pattern. In fact, higher doses may predict failure. In a study of 1151 consecutive nulliparous patients (Wen and colleagues, 2001), the likelihood of progressing to a vaginal delivery decreased at or beyond an oxytocin dose of 36 mU/min. However, at a dose of 72 mU/min, half of nulliparas delivered vaginally. This must be weighed against the fact that if the FHR is reassuring and labor has arrested (i.e., contractions not adequate [<200 Montevideo units]), there are no apparent risks to oxytocin doses greater than 48 mU/ min. It should be kept in mind that oxytocin is a homolog to vasopressin; therefore, it has significant antidiuretic properties and when infused at doses greater than 20 mU/min may result in renal retention of free water. Infusion of oxytocin in aqueous fluid in appreciable amounts can result in water intoxication and hyponatremia. which can lead to coma, convulsions, and even death.

## **COMMON ERRORS**

The provider must be prepared to handle both maternal and fetal complications before an induction is initiated. Once applied (except for the dinoprostone insert, which can be removed by using its retrieval system) prostaglandins cannot be removed or reduced like oxytocin. For practical purposes, all of these ripening techniques can be performed in the evening and overnight, with planned oxytocin administration or amniotomy the following morning. The provider must also ensure that the resources are available to perform an immediate delivery (either vaginally or by cesarean section) and newborn resuscitation, if necessary.

## **COMPLICATIONS**

- Uterine hyperstimulation (defined as stimulated uterine contractions of moderate to strong intensity in >50% of contractions in a 10-minute segment) and possible premature separation of placenta
- Failed induction with increased risk of cesarean delivery
- Abnormalities or changes in FHR pattern
- Premature infant if dates calculated incorrectly
- Fetal acidosis
- Fetal distress
- Infant with low Apgar scores
- Precipitous delivery
- Prolapsed umbilical cord
- Maternal or newborn infection
- Uterine rupture

## POSTPROCEDURE MANAGEMENT

The goal of an induction is an otherwise normal vaginal delivery. However, the provider must be prepared to manage all situations

that can occur during induction and delivery. Should hyperstimulation occur, the FHR pattern should be assessed immediately. If at that time, or any other time, the FHR pattern is not reassuring, immediate intrauterine resuscitation should be initiated. This includes an IV fluid bolus of 1000 mL, lateral positioning of the mother, and oxygen administration at 10 L/min through a nonrebreather face mask to increase fetal oxygenation. If hyperstimulation occurs and a dinoprostone insert is being used, it should be removed: if oxytocin is being used it should be stopped. Likewise, an oxytocin infusion should be halted if a nonreassuring FHR occurs. Some protocols suggest oxytocin can be restarted when indicated (hyperstimulation resolved and FHR reassuring) at half the dose used when stopped. If other pharmacologic methods are being used, they cannot be removed, so terbutaline 0.25 mg as a subcutaneous injection can be administered and repeated as necessary. If the FHR pattern does not respond in a satisfactory manner, the provider should proceed to an immediate operative delivery. If the FHR pattern is reassuring despite the uterine hyperactivity, the oxytocin should be titrated down until the uterine response is acceptable.

## **CPT/BILLING CODES**

No specific CPT codes exist for labor induction. According to the CPT manual, labor that is preterm, post-term, induced, augmented or otherwise complicated is not routine and requires additional time and resources. The clinician should code these situations with hospital Evaluation and Management codes.

99356 Prolonged physician service in the inpatient setting, requiring direct (face-to-face) patient contact beyond the usual service (e.g., maternal fetal monitoring for high-risk delivery or other physiological monitoring); first hour (list separately in addition to code for inpatient Evaluation and Management service).

99357 Each additional 30 minutes (list separately in addition to code for prolonged physician service).

And, if prolonged, but not face-to-face, care

99358 Prolonged Evaluation and Management service before and/ or after direct (face-to-face) patient care (e.g., review of extensive records and tests, communication with other professionals and/or the patient/family); first hour (List separately in addition to code[s] for other physician service[s] and/or inpatient or outpatient Evaluation and Management service).

## **ICD-9-CM DIAGNOSTIC CODES**

Multiple possible diagnostic codes exist to support the induction of labor. The fifth digit (X) is required for codes 640 to 648 and 651 to 659 to denote the following common codes:

- Unspecified
- 1 Delivered, with or without mention of antepartum condition
- 2 Delivered, with mention of postpartum complication
- 3 Antepartum condition or complication

- Postpartum condition or complication
- 641.2X Premature separation of placenta
- 642.0X Benign essential hypertension complicating pregnancy, childbirth, and the puerperium
- 642.1X Hypertension secondary to renal disease complicating pregnancy, childbirth, and the puerperium
- 642.4X Mild or unspecified preeclampsia
- 642.5X Severe preeclampsia
- 642.6X Eclampsia
- 642.7X Preeclampsia or eclampsia superimposed on preexisting hypertension
- 645.1X Post-term pregnancy, 40 to 42 weeks' gestation, delivered with or without antepartum condition
- 645.2X Prolonged pregnancy, beyond 42 weeks' gestation, delivered with or without antepartum condition
- 646.2X Unspecified renal disease, without mention of hypertension
- 648.0X Diabetes mellitus
- 648.8X Gestational diabetes
- 656.1X Rh isoimmunization
- 656.2X Isoimmunization from other and unspecified blood-group incompatibility
- 656.3X Fetal distress
- 656.4X Intrauterine fetal death
- 656.5X Intrauterine growth retardation
- 658.1X Premature rupture of membranes (membranes ruptured <24 hours before onset of labor)
- 658.2X Delayed delivery after spontaneous or unspecified rupture of membranes (ruptured >24 hours before onset or prolonged rupture of membranes)
- 658.4X Infection of amniotic cavity
- 659.0X Failed mechanical induction
- 659.1X Failed medical or unspecified induction
- 659.7X Abnormality in fetal heart rate or rhythm

# **AMNIOTOMY**

Rebecca H. Gladu

Amniotomy, or artificial rupture of the membranes, is often used in the management of laboring patients. This procedure is used to prepare for insertion of an intrauterine pressure catheter monitor or a fetal scalp electrode, to stimulate labor progress in active management protocols, to check the volume of amniotic fluid, to check for the presence of meconium where the fetal tracing may indicate difficulty, and to produce a presumably more rapid labor. Many studies and reports suggest that with artificial rupture of membranes labor is shortened slightly, but there is no evidence that a shorter labor in any way benefits the mother or fetus. If amniotomy is performed, an aseptic technique should be used. The clinician should be careful during amniotomy to avoid dislodging the fetal head and to avoid cord prolapse (if the head is not fully engaged when amniotomy is performed, it increases the risk of prolapse). Overall, amniotomy is a simple and relatively safe procedure that may be beneficial to the management of some women in labor.

**EDITOR'S NOTE:** Amniotomy should not be performed routinely. Some experts perform it only if there is a strong indication; in most cases, nature will run its course without an intervention. Depending on the station of the fetal head, any attempt to rotate it and change the position (e.g., from occiput posterior to occiput anterior) should probably be made before amniotomy.

## **INDICATIONS**

- Necessity of internal uterine or fetal monitoring when membranes are intact
- Active management of labor protocol
- Questionable meconium
- Induction of labor
- Hastening labor

NOTE: Although a fetal scalp electrode can be applied through the amniotic membranes, performing an amniotomy first will usually simplify that procedure (see Chapter 168, Fetal Scalp Electrode Application). Although a fetal scalp electrode can be applied through the membranes to create a "slow leak" of fluid, perhaps enhancing engagement (as opposed to an "abrupt" amniotomy), there is no evidence to support the use of a fetal scalp electrode in this manner.

## **CONTRAINDICATIONS**

## **Absolute**

- Malpresentation
- Cord palpable below or near fetal head
- Unstable lie
- Suspected velamentous insertion of umbilical cord

## **Relative**

 Presentation unknown or not fully engaged—if head not fully engaged, it increases risk of prolapse

- Cervix dilated less than 3 cm, or patient not in active labor
- Patient refusal

## **EOUIPMENT AND SUPPLIES**

- Amniotomy hook (Fig. 164-1) or amniotomy glove (Fig. 164-2).
- Sterile gloves and lubricant.
- Absorbent pads and towels to be placed under the patient.
- Fetal monitor.
- Tocolytics should be available, especially if the patient is being augmented.
- Equipment necessary for the clinician to observe universal blood and body fluid precautions.

## **PRECAUTIONS**

Risks to the patient (and infant) include the following:

- Infection such as chorioamnionitis (especially if labor is prolonged)
- Need for antibiotics (especially if labor is prolonged)
- Bleeding
- Cord prolapse
- Uterine tetany
- Fetal scalp scratch or laceration

# PREPROCEDURE PATIENT EDUCATION AND FORMS

The procedure should be explained to the patient as well as its possible benefits, risks, and any alternatives (see patient consent form available online at www.expertconsult.com). The patient should be informed about the risk of cord prolapse and the precautions the clinician will take to avoid this as well as all possible complications. If the procedure is being used to stimulate labor progression, it should be clear to the patient that sometimes this procedure alone does not reduce the length of labor. On the other hand, the contractions may become more frequent and very strong, even requiring a medication to block them. The possible increased risk of infection (and need for antibiotics) and bleeding should be explained. Rupture of membranes commits the patient to delivery, usually within 24 hours. After 24 hours, the risk of chorioamnionitis increases significantly, so cesarean delivery may be indicated or necessary. There is a rare chance that the infant's head could be scratched or cut.

## **TECHNIQUE**

## **Amniotomy Hook**

1. The patient should attempt to relax in the recumbent position with feet together and hips externally rotated (i.e., frog-legged) or in stirrups. Observe universal blood and body fluid precautions when performing this procedure. The fetal heart rate should be

Figure 164-1 Amniotomy hook.

recorded before, during, and after amniotomy. Perform a cervical examination to confirm that the membranes are intact, with at least 3 cm dilation, and that the head is well applied. The presence of an umbilical cord should be excluded.

- 2. Introduce the second and third digits (index and middle fingers) of the nondominant hand, palmar side up, into the vagina. Insert the fingertips past the cervical lip, into the uterus, and against the membranes. Make sure that the fingers are truly against the membranes and not against a thin cervical lip.
- 3. Grasping the amniotomy hook with your dominant hand, introduce the tip into the vagina and into a position between the two fingers on the nondominant hand already applied against the membranes (Fig. 164-3). The hook should be pointed downward (away from the membranes). Ask an assistant to apply fundal and suprapubic pressure to reduce the risk of cord prolapse. This maneuver may also increase the amount of fluid bulging between the membranes and the head. This bulge should mimic a bag, hence the description of the mother's "bag of water." Avoid compressing the membranes too tightly against the infant's head with the nondominant hand; this may make it more difficult to hook the bag.
- 4. Invert the hook upward (i.e., rotate it 180 degrees), apply pressure to the bag with the hook, and rupture the bag with a single motion of the sharp hook. If successful, fluid should run from the vagina. If no fluid appears, this step may be repeated two or three times until fluid is noted to flow from the vagina. If these attempts are unsuccessful, and the bag is still palpable, relax the fingertips away from the membranes and move them slightly. This will allow you to attempt hooking the bag from a different direction. Make sure the fingers of your nondominant hand are against the

**Figure 164-2** Amniotomy glove: AROM-COT. (Courtesy of Utah Medical Products, printed with permission.)

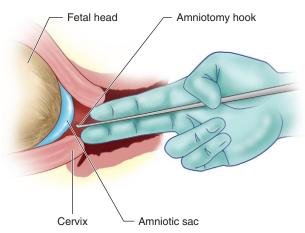

Figure 164-3 Proper insertion of amniotomy hook.

membranes (and not the cervix) and again attempt to rupture the bag with a single motion of the hook. The bag may be quite slippery, so it may take several attempts, redirecting several times, before the amniotomy is successful. Apply varying amounts of pressure against the membranes with the nondominant hand with each attempt. If unsuccessful at this point, request a new hook because the hook may be defective. If there is little fluid palpable (no bag) at the beginning of the procedure, instead of rupturing the membranes or "breaking the bag of water" with the hook, the clinician should attempt to grasp and tear the membranes with the hook. If successful, even though fluid was not apparent as a bag before amniotomy, it may still run out of the vagina. Without a full bag, the sensation of performing amniotomy is quite different; the clinician may have the sensation of merely scratching the fetal scalp with the hook. As long as the clinician is sure that the presentation is vertex and only gentle attempts are made at hooking the bag, it should minimize the risk of actually scratching or lacerating the infant's scalp.

- 5. After successful amniotomy, remove the hook. Note the volume of fluid that has drained. If very little fluid has drained, no prior ultrasonography was performed, and the membranes were thought to be previously intact, the diagnosis of oligohydramnios should be considered. If so, be prepared for additional resuscitative needs for the infant, especially if it is a small infant. (Also, don't forget to check for a second infant!)
- 6. Keep the fingers of the nondominant hand applied against the fetal head as fluid is allowed to leak out, noting the color of the fluid (clear or meconium stained). Be sure to confirm that the umbilical cord is not prolapsing.
- Remove the fingers and observe the fetal monitor for any signs of distress, such as fetal bradycardia or tachycardia.

## **Amniotomy Glove**

Steps 1 and possibly 2 are the same as with the amniotomy hook except that the finger cot is placed on the index finger with the hook pointing toward the palm of the hand, and then against the amnion to rupture it. This simplifies the procedure and prevents the clinician from having to use an instrument blindly. Clinician preference dictates whether the cot is placed on the dominant hand or the nondominant hand. No matter which hand is used for the cot, the other hand can be inserted behind the cervix and against the membranes, as with the amniotomy hook. It can then be used after amniotomy to stabilize the head. Alternatively, because only one hand needs to be inserted into the vagina to perform the amniotomy, the other hand can be used to apply fundal or suprapubic pressure, which can then be released after successful amniotomy. Universal blood and body fluid precautions should be observed when performing this procedure.

### 1120 OBSTETRICS

- Use the finger cot to apply pressure to the membranes with the sharp device. This step may be repeated until fluid is noted to flow from the vagina.
- 4. See steps 4 through 7 from the Amniotomy Hook section.

#### SAMPLE OPERATIVE REPORT

See the sample operative report online at www.expertconsult.com.

#### **COMMON ERRORS**

- Failure to fully rupture the amnion. Should this error occur, reposition the hand and repeat the procedure. Occasionally, only a partial amniotic tear is accomplished or only one layer is ruptured, requiring repetition of the procedure ("the double bag").
- Mistaking a thinned cervical lip for the amnion. This mistake can cause the patient some discomfort if she is not under some type of anesthesia.

## **COMPLICATIONS**

- Fetal distress
- Failure to induce or augment labor
- · Increase in pain sensation with labor
- Prolapsed cord
- Infection due to prolonged rupture of membranes
- Possibly increased risk of cesarean delivery

### POSTPROCEDURE MANAGEMENT

Observe the patient and fetus for signs of distress, such as fetal heart rate decelerations on the fetal monitor. Ensure that the cord did not prolapse and that the amniotomy hook did not lacerate the cervix or infant.

# **POSTPROCEDURE PATIENT EDUCATION**

The patient should be instructed to expect the leakage of fluid. Should she develop any pain or bleeding after the procedure, she should notify the clinician immediately. In general, most patients are not given a handout about the procedure for postprocedure education.

## **CPT/BILLING CODES**

Amniotomy is not a separate billable procedure. It is considered part of labor management.

## **ICD-9-CM DIAGNOSTIC CODES**

- 656.83 Meconium-stained fluid, affecting management of pregnancy or delivery, antepartum complication
- 656.83 Fetal distress, NOS, affecting management of pregnancy or delivery, antepartum complication
- 657.03 Polyhydramnios, antepartum condition or complication
- 661.11 Secondary uterine inertia, arrested active phase of labor or hypotonic uterine dysfunction, delivered with or without mention of antepartum condition
- 662.01 Prolonged labor, first stage, delivered with or without mention of antepartum condition
- 662.21 Prolonged labor, second stage, delivered with or without mention of antepartum condition

# ANTEPARTUM FETAL MONITORING

Stephen D. Ratcliffe

Since the 1960s, certain fetal heart rate patterns have been associated with poor outcomes. Subsequently, several techniques for evaluating fetal well-being and uteroplacental function have evolved. Although there is currently no "best test," largely because of a lack of randomized clinical trials (RCTs), the majority of centers use a combination of fetal movement counting (FMC), the nonstress test (NST), the biophysical profile (BPP), the modified BPP, and the contraction stress test (CST). Some also use arterial Doppler velocitometry. FMC, NST, modified BPP, and CST are covered in this chapter, Doppler velocitometry will be discussed, and the BPP is discussed in Chapter 172, Obstetric Ultrasonography.

Whether NST, CST, modified BPP, or BPP is used, a negative test is very reassuring, with negative predictive values (no fetal death within a week of the test) of 99.8% or higher. Unfortunately, positive predictive values are quite low, ranging from 10% to 40%, which can be problematic for the clinician. Additional challenges include deciding when to start and the frequency of testing. Most experts start testing high-risk pregnancies at 32 to 34 weeks. Pregnancies with severe complications may need testing as early as 26 to 28 weeks.

## **DOPPLER VELOCITOMETRY**

Real-time ultrasonography machines equipped with Doppler technology can assess arterial velocity and flow. Fetal Doppler studies were initially used to evaluate the placenta by measuring umbilical artery outflow. However, with improved technology, multivessel evaluation became possible. Subsequently, this antenatal test has been the subject of more RCTs than any other antenatal test. The current position of the American College of Obstetricians and Gynecologists (ACOG) on umbilical artery velocitometry is that there is no benefit other than in pregnancies with suspected growth restriction. Its use may alert the clinician to the need for an additional study such as a BPP, continuous fetal monitoring, or delivery.

# **FETAL MOVEMENT COUNTING**

Both human and animal studies indicate that a fetus in trouble (having hypoxemia) will reduce its oxygen requirements by reducing its activity. As a result, FMC is a potentially useful tool for monitoring the fetus during the third trimester of pregnancy. FMC is commonly used to monitor high-risk pregnancies, although there is no RCT evidence to support its use.

Studies of women presenting with decreased fetal movement have produced variable results, ranging from no increase in adverse outcomes to a 3.8% perinatal mortality rate in a cohort of 599 low-risk pregnancies. Grant and colleagues (1989) performed the largest RCT (N = 68,000), which demonstrated that the routine use of FMC in low-risk pregnancies did not improve perinatal outcomes. Although the study authors did not find improved outcomes with FMC, they did conclude that maternal perceptions of decreased fetal movement were as good as formally counted and recorded fetal movement.

#### Indications

The clinician needs to decide when to use FMC.

- All pregnancies as a routine practice: The evidence does not support daily FMC in all pregnancies (Mangesi and Hofmeyr, 2007). It does support being on the alert for overall decreased fetal movement. Patients who report decreased fetal movement should be instructed to contact their clinicians or to report to labor and delivery.
- High-risk pregnancies: RCTs have not been performed to study the use of FMC in these patients. However, it is a common practice to recommend FMC as a secondary method of fetal surveillance in these pregnancies.

### **Contraindications**

- Impaired mental status or significant linguistic or cultural barrier—any barrier preventing adequate communication or the proper use of FMC could cause screening errors or failures.
- Mother unable to sense fetal movements—there are cases where
  the clinician can actually see the fetus moving (e.g., during a
  routine visit, while measuring the fundal height, or otherwise
  observing the anterior abdomen), yet the patient cannot sense
  the movement. It may not be possible to use FMC with these
  patients.

# **Technique**

- 1. The patient should be instructed in the count-to-ten method of FMC (see patient education handout online at www. expertconsult.com). The "Cardiff" count-to-ten method has been studied and compared with the Sadovsky method (three 30- to 60-minute counts at preset times each day) and the Rayburn method (FMC for 60 minutes, once a day). There is a higher patient compliance rate with the count-to-ten method. Instruct the patient to count 10 fetal movements (e.g., swishes, rolls, kicks). The test is complete and considered to be "reassuring" when 10 movements are counted in less than 2 hours. Tests are usually performed in the evening and are often completed within 20 minutes.
- The patient is instructed to report to labor and delivery or to notify her clinician if 10 movements are not recorded within a 2-hour period. Such a result is a "nonreassuring" screening test.

## **Complications**

Unfortunately, FMC produces frequent false-positive results. A non-reassuring FMC may be further complicated by false-positive follow-up antenatal testing results. These abnormal findings often result in the decision to induce labor, thereby unnecessarily exposing the mother and child to the risks of induction.

# **Interpretation of Results**

A reassuring test is described in the earlier section on Technique. Patients arriving at labor and delivery with a complaint of decreased fetal movement usually undergo an NST. A normal or reactive NST is sufficient to assess fetal well-being. If the NST is not reassuring, then additional antenatal fetal testing will be necessary, such as a BPP or a CST.

### **NONSTRESS TEST**

The NST was introduced in the United States in the early 1970s. Despite the lack of RCT evidence to support its use, the NST is the workhorse of antenatal fetal surveillance. It is usually the first-line test to evaluate high-risk pregnancies and fetal well-being. The NST uses fetal monitoring to document fetal heart rate accelerations that occur in conjunction with fetal movements. Extensive clinical observations have shown a strong correlation between absent or less frequent fetal heart rate accelerations and progressive fetal hypoxia. Conversely, the presence of fetal heart rate accelerations associated with fetal movement (reactive NST) is a reassuring indicator of good fetal health. Although this is not a complex procedure, the clinician must be adept at the proper interpretation of the NST. Important considerations include the indication for testing, gestational age, and any known congenital anomalies or maternal medical conditions. The clinician should also know whether the patient has taken any medications (e.g., narcotics, barbiturates) that might affect the reactivity of the fetal tracing.

#### **Indications**

The NST is used to monitor high-risk pregnancies as early as 32 weeks' gestation. Some of these high-risk conditions include the following:

- Suspected or confirmed intrauterine growth restriction (IUGR; may also use umbilical artery Doppler velocitometry)
- Maternal or gestational diabetes
- Hypertensive disorders of pregnancy
- Prolonged or post-term pregnancy
- Decreased fetal movement
- Maternal trauma
- Other maternal or fetal condition posing risk to the fetus (e.g., renal disease, multiple gestation, substance abuse, prior fetal demise, trauma)

Some clinicians use the NST as early as 26 weeks' gestation. Different criteria are used to define a reactive or reassuring fetal heart rate tracing before 32 weeks (see Interpretation of Results section). As experience has evolved with the NST, the interval between testing has shortened. Originally set rather arbitrarily at 7 days, more frequent testing is advocated for women with prolonged or post-term pregnancy, type 1 diabetes mellitus, IUGR, or gestational hypertension. In these circumstances, many experts perform twice-weekly NSTs, with more frequent testing for maternal or fetal deterioration. Some even perform NSTs daily, or more frequently, especially for severe preeclampsia remote from term.

### **Contraindications**

There are no specific contraindications to performing an NST, although the test should be aborted if the mother goes into labor and there is marked fetal intolerance of labor.

## Equipment

- Fetal heart rate and uterine pressure monitor (Fig. 165-1)
- Blood pressure cuff

**Figure 165-1** Intrapartum fetal and uterus monitor. (Courtesy of GE Medical Systems.)

- Fetal stimulation device (vibroacoustic stimulator [VAS], such as an artificial larynx)
- Ultrasonic gel for monitor
- Bed or comfortable reclining chair

## **Preprocedure Patient Education**

Before the NST is performed, the patient should be given a handout outlining the procedure and the steps to follow (see sample patient education handout online at www.expertconsult.com). Many testing centers use standardized protocols in an attempt to minimize confounding environmental variables. These protocols encourage the patient to eat about 2 hours before the NST, to *not* smoke or take sedative drugs before the test, and to remain sedentary during the hour before testing.

### **Technique**

- 1. Place the patient in a semirecumbent (semi-Fowler's) position, tilted slightly to her left or with slight left lateral hip displacement. She can also be seated in a reclining chair at a 30- to 45-degree angle.
- 2. Apply external uterine and fetal monitors (tocodynamometer and Doppler) to record any uterine contractions and the fetal heart rate. Record the patient's blood pressure before the test to make sure she does not have supine hypotension, which could cause a falsely abnormal test result. Check the blood pressure every 10 to 15 minutes during the test.
- 3. Ask the patient to report or record any fetal movements.
- 4. Monitor the patient for a 30-minute baseline period. Two additional 30-minute monitoring periods should be considered if the tracing is nonreactive.
- 5. If there is insufficient fetal movement in the first or second 30-minute observation period, there is strong evidence (based on multiple RCTs) supporting the use of a fetal stimulation device such as a VAS to induce fetal movements. According to ACOG, this can be used for 3 seconds and repeated up to three times. Use of a VAS does not decrease the sensitivity of the NST or result in an increase of falsely reassuring tests. One investigator found that using the VAS with every NST shortened the average time for the NST from 24 to 15 minutes.

## **Complications**

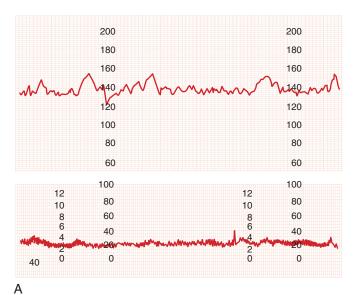

False-positive results can occur. Such results may lead to premature interventions that could lead to iatrogenic perinatal complications, such as an unnecessary cesarean intervention with its associated complications.

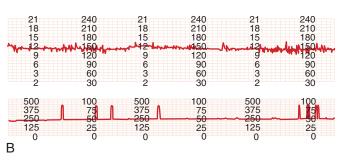

## Interpretation of Results

A fetal tracing is considered reactive if there are two or more accelerations of more than 15 beats per minute (bpm) lasting for at least 15 seconds but not more than 2 minutes (Fig. 165-2A). ACOG considers accelerations occurring without fetal movement to also be reactive.

Because the premature fetus has less pronounced heart rate accelerations than the more mature fetus, the National Institute of Child Health and Human Development (1997) defines a 10-bpm acceleration lasting for 10 seconds to be a reassuring or reactive NST for fetuses before 32 weeks' gestation.

In a low-risk pregnancy, nonreactivity (Fig. 165-2B) usually indicates the infant is sleeping. The clinician should extend the observation period for as long as 90 minutes total to decrease the likelihood of a false-positive test result. Alternatively, the clinician may safely use VAS to induce fetal movements. In addition, make sure that the patient undergoing an NST is in a semirecumbent position to avoid supine hypotension and a false positive (nonreactive) NST.

**Figure 165-2 A,** Reactive (normal) nonstress test (NST), with two or more accelerations of 15 beats per minute lasting for at least 15 seconds but not more than 2 minutes. Note the fetal heart rate in the upper tracing accelerates with fetal movement, which is noted by the vertical marks on the lower tracing. The vertical marks are made when the mother presses the button as she perceives fetal movement. **B,** Nonreactive (abnormal) NST. Although the mother perceives fetal movement, as noted by the vertical marks on the lower tracing, there are no fetal heart rate accelerations. (A, From Biophysical profile scoring. In Rumack CM, Wilson SR, Charboneau JW, Johnson J-A [eds]: Diagnostic Ultrasound, 3rd ed. Philadelphia, Mosby, 2005, Fig. 46-2; **B,** From Antepartum fetal evaluation. In Gabbe SG, Niebyl JR, Simpson JL, et al [eds]: Obstetrics: Normal and Problem Pregnancies, 5th ed. New York, Churchill Livingstone, 2007, Fig. 11-7.)

The clinician must take into account the risk status of the patient and the indication for ordering an NST when interpreting a nonreactive NST and before proceeding with further interventions. The positive predictive value of an abnormal NST ranges from 15% for evaluating a post-term pregnancy to 69% for evaluating IUGR. Hence, false-positive tests are common.

Reactive NSTs that have no other abnormalities on the tracing (e.g., variable decelerations) have a very low false-negative rate (2 in 1000). Combining an NST with an amniotic fluid index (AFI; see Chapter 172, Obstetric Ultrasonography, for a more complete discussion of evaluating amniotic fluid volume) produces a "modified BPP" and results in an even more sensitive test, with a false-negative rate of 0.8 per 1000.

In addition to obtaining a modified BBP, options available for the clinician to evaluate a fetus with a persistently nonreactive NST include BPP, CST, or proceeding with induction when the infant is mature and the mother has a favorable cervix. A sample flowchart for the management of an NST is shown in Figure 165-3. In settings that do not routinely perform modified BPPs, the occurrence of repetitive variable decelerations in an otherwise reactive NST should prompt a measurement of the AFI. This subgroup of fetuses is at increased risk of cord compromise during labor.

# **Postprocedure Patient Education**

It is essential that patients receive a detailed explanation of the results of the NST and the specific signs and symptoms (e.g., decreased fetal movement, vaginal bleeding, leakage of fluid) for which they should watch. Patients should receive explicit instructions regarding follow-up appointments and when to go to labor and delivery.

# MODIFIED BIOPHYSICAL PROFILE

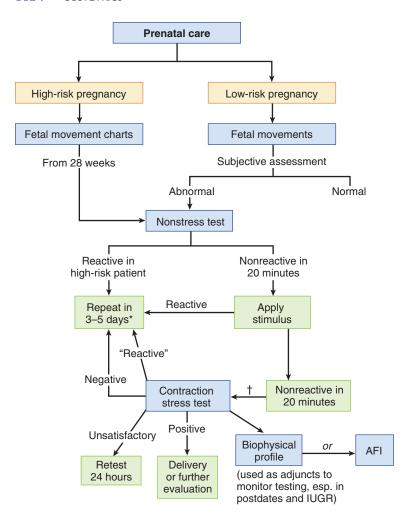

Although a normal weekly BPP result can somewhat ensure fetal well-being, this is a labor-intensive process and requires a high level of expertise—a sonographer or clinician trained to perform and interpret ultrasonography scans. Therefore, the modified BPP (NST combined with an AFI) was developed in the late 1980s. An AFI less than 5 cm, or oligohydramnios, is suspected to be due to decreased urine production, in turn due to decreased fetal renal blood flow, which suggests uteroplacental insufficiency. One of the early studies reported that it took only about 10 minutes to perform a modified BPP when a VAS is used for the NST; if nursing staff are trained to perform an AFI, they can perform the entire modified BPP. In centers using modified BPPs for surveillance, most perform it twice weekly. In 1996, Miller and colleagues reported results from more than 54,000 modified BPPs in 15,400 high-risk pregnancies and described a false-negative rate of 0.8 per 1000 and a false-positive rate of 1.5%. Subsequently, ACOG endorsed the modified BPP as an acceptable means of antepartum monitoring.

## **Indications**

- High-risk pregnancy, especially a prolonged or a post-term pregnancy
- A follow-up evaluation of a suspect or abnormal NST

## **Equipment**

- Real-time ultrasonography machine with a 3-MHz or higher transducer. Among state-of-the-art machines, differences between different manufacturers are primarily subjective. (See the Suppliers section of Chapter 172, Obstetric Ultrasonography.)
- Bed
- Ultrasonic gel
- Towels to remove gel when study completed
- Appropriate forms for documentation

**Figure 165-3** Sample flowchart for management of the nonstress test (NST) and modified biophysical profile. AFI, amniotic fluid index; IUGR, intrauterine growth retardation. \*"Twice weekly" NSTs recommended. †"Prolonged" NST may be repeated in 2 to 3 hours. (Courtesy of Kent Petrie, MD, Vail, Colo.)

## **Preprocedure Patient Education**

Before the modified BPP is performed, the patient should be given a handout outlining the procedure and the steps to follow (see sample patient education handout online at www.expertconsult.com). Unlike in nongravid pelvic ultrasonography, the patient will not need a full bladder. The patient should also be aware that although the sonogram will demonstrate a fetus and probably fetal activity, it will be used only to evaluate the amount of amniotic fluid. See Chapter 172, Obstetric Ultrasonography, for more Preprocedure Patient Education.

#### **Technique**

- 1. After the NST has been completed, place the patient in the recumbent or a semirecumbent (semi-Fowler's) position, tilted slightly to her left or with slight left lateral hip displacement.
- 2. The uterus is divided into four quadrants. The ultrasound transducer is then held in a vertical and sagittal alignment (marker dot on the probe turned toward the mother's head [cephalad]). With the patient supine, the transducer is held perpendicular to the plane of the floor and aligned longitudinally with the mother's spine. Starting in one quadrant, the pocket of fluid with the largest vertical dimension is identified, measured, and recorded. Care must be taken not to include segments of the umbilical cord in the measurement. Coiled cord can fill the space and appear to be fluid.
- 3. This procedure is repeated in each quadrant and the values summed. If the sum (AFI) is less than 8 cm, perform the four-quadrant evaluation three times and average the values.

#### Interpretation of Results

Most published results considered a nonreactive NST or an AFI less than 5 cm to be abnormal, and abnormal modified BPP results are usually followed up with a BPP, a CST, or delivery if the fetus is mature and the cervix favorable (see Fig. 165-3). At least one study (Nageotte and colleagues, 1994) found that when patients with an abnormal modified BPP were randomized to either BPP or CST, the CST resulted in a higher false-positive rate.

**NOTE:** On noting an abnormal AFI, most clinicians will either immediately perform a BPP or call a clinician capable of performing a BPP.

## **CONTRACTION STRESS TEST**

The CST was one of the earliest antepartum fetal surveillance tests, and it is used infrequently today. It is designed to identify fetuses at risk from uteroplacental insufficiency and is usually performed in a hospital setting. A CST is usually a secondary antenatal test used when an NST, modified BPP, or BPP does not provide the reassurance needed to continue an expectant course of pregnancy management. The basis of the test is to determine whether uterine contractions cause late decelerations in the fetal heart tracing. A secondary use of the CST is to determine if regular uterine contractions provoke recurrent variable decelerations suggestive of umbilical cord compression.

In the setting of uteroplacental insufficiency, fetal oxygen reserves are diminished. As a result, a brief hypoxic episode from a uterine contraction can cause a vagally mediated fetal bradycardia

that in turn produces a late deceleration. Hypoxia can also directly affect the fetal myocardium and trigger a late deceleration.

Research in the mid-1960s demonstrated that late decelerations were associated with adverse perinatal outcomes such as an increased stillbirth rate and low Apgar scores. Ray and colleagues (1972) instituted the *oxytocin challenge test* because it relied on an infusion of synthetic oxytocin. Clinicians may choose to use spontaneous contractions or those induced by breast stimulation in place of oxytocin administration. This simplification of the procedure has also resulted in the procedure being called the CST.

In case series, the CST has been shown to be the most sensitive test for antenatal fetal surveillance, with a fetal loss rate of 0.03% within 1 week of a negative or normal CST, compared with a 0.08% loss rate for BPP and modified BPPs, and a 0.18% loss rate for a normal or reassuring NST. Disadvantages to the CST include the length of time required for testing (an average of 90 minutes in one study) and the need to have intravenous access if oxytocin is used.

#### **Indications**

- Suspected fetal compromise in a high-risk pregnancy
- Follow-up evaluation of a suspect or abnormal NST, modified BPP, or BPP

#### **Contraindications**

#### **Absolute**

If labor is contraindicated, the CST is contraindicated (e.g., prior premature labor and considerable cervical dilation and effacement have already occurred, incompetent cervix with nonmature fetus, placenta previa, classic cesarean scar).

#### Relative

A breech or other fetal indication for cesarean is a relative contraindication.

## **Equipment**

- Fetal heart rate and uterine pressure monitors (see Fig. 165-1)
- Ultrasonic gel for monitors
- Blood pressure cuff
- Intravenous setup
- Terbutaline
- Bed or comfortable reclining chair

#### **Preprocedure Patient Education**

Give the patient a teaching guide explaining the CST and answer any questions she may have. Risks, benefits, and alternatives should be explained and informed consent obtained.

### **Technique**

- 1. Place the patient in a semirecumbent (semi-Fowler's) position, tilted slightly to her left, or with slight left lateral hip displacement. She can also be sitting in a reclining chair at a 30- to 45-degree angle. Attach fetal and uterine monitors.
- 2. Take a baseline blood pressure to ensure that supine hypotension, which could cause a false-positive CST result, does not exist. Repeat every 10 to 15 minutes during the test.
- 3. Record a baseline fetal heart rate tracing for 20 to 30 minutes to assess for reactivity. Concurrently, the uterus should be monitored to determine whether there are spontaneous uterine contractions. Subcutaneous terbutaline, which relaxes uterine muscle in the event of serious uterine hyperstimulation and hypertonic contractions, should be readily available. If there are

- adequate spontaneous contractions (three or more per 10 minutes, lasting 40 seconds or longer), monitor the fetal heart rate during these contractions, and the study is completed.
- 4. If there are not enough adequate spontaneous contractions, after obtaining the baseline NST ask the patient to stimulate one nipple by massaging it through her clothing for about 2 minutes (or less if a contraction starts). She can restart the stimulation in 5 minutes if three contractions do not occur in 10 minutes. If no contraction is induced after 2 minutes, have her stop the stimulation for 2 minutes before repeating the process on the other side. If intermittent stimulation does not achieve the desired uterine contractions, bilateral stimulation should be performed for about 10 minutes.
- 5. Once an adequate contraction pattern is achieved, the breast stimulation should be stopped. Uterine hyperstimulation patterns (more than five contractions per 10 minutes or contractions lasting 90 seconds or more) occur in 3% to 4% of CSTs using breast stimulation. Provide continuous fetal and uterine monitoring.

**NOTE:** The nipple-stimulation CST is frequently used because it bypasses the need for placing an intravenous line. If successful, it also reduces the testing time.

6. If nipple stimulation does not produce an adequate contraction pattern, oxytocin can be administered. Initiate the intravenous infusion of oxytocin at 0.5 to 1.0 mU/min. This rate may be increased every 15 minutes by increments of 0.5 to 1.0 mU/ min until regular uterine contractions are achieved. (Another published protocol doubles the infusion rate every 20 minutes.) An adequate CST has been achieved when there are three contractions lasting 40 seconds or longer within a 10-minute period. If oxytocin is used, the majority of patients will achieve this contraction pattern by the time they reach an infusion level of 4 to 8 mU/min. Uterine hyperstimulation occurs during oxytocin challenge testing in about 1% of patients and generally responds to stopping the oxytocin infusion. If the contractions do not decrease rapidly after stopping the oxytocin, administer subcutaneous terbutaline, 0.25 to 0.5 mg.

# **Complications**

- Uterine hyperstimulation often provides a false-positive CST that may lead to improper management if not correctly identified.
- Fetal distress requiring an emergency intervention is a rare complication of uterine hyperstimulation. Uterine hyperstimulation almost always resolves if the oxytocin infusion or breast stimulation is stopped. If this is not sufficient, subcutaneous terbutaline may be used as described previously.

#### **Interpretation of Results**

"Negative" test results are reassuring. "Positive" or "suspect" results are causes for concern. A CST is positive if more than 50% of the contractions are accompanied by late decelerations in the absence of uterine hyperstimulation. The reactivity of the fetal tracing is an important factor to weigh when evaluating a positive CST. A *reactive*, positive CST is associated with a high incidence of false-positive results, whereas a *nonreactive*, positive CST has a much higher predictive value for identifying a compromised fetus (Fig. 165-4).

A suspect or equivocal CST is one in which less than 50% of the contractions result in late decelerations. The result is also considered equivocal if the decelerations occur during hyperstimulation because it cannot be determined whether the CST is negative or positive.

A negative CST is one in which no late decelerations occur when the contraction frequency is at least three per 10 minutes. In addition, no significant variable decelerations should occur. A

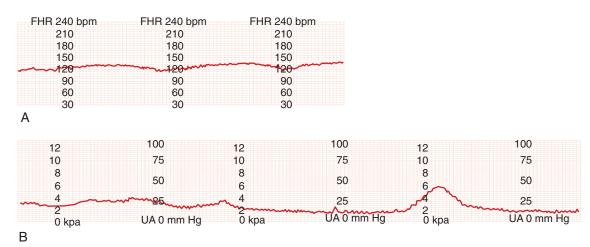

Figure 165-4 Nonreactive positive contraction stress test. A, Fetal heart rate (FHR). B, Uterine activity (UA; i.e., contractions).

negative CST that is *nonreactive* is uncommon. This test result deserves further scrutiny to determine if the cause is a medication (e.g., narcotics, phenobarbital), a fetal central nervous system defect, subtle fetal distress, or a premature infant.

A positive or suspect CST result should be given careful consideration. Maternal factors that affect placental function such as dehydration or hypotension should be addressed. If improvement in the fetal heart rate tracing cannot be attained, and if fetal pulmonary maturity has been confirmed, labor is often induced.

# **Postprocedure Education**

A CST must be interpreted in the context of the patient's overall clinical condition. Because CSTs are usually reserved for high-risk patients, clear postprocedure instructions for these patients are essential. Even patients with negative CSTs require explicit instructions for follow-up antenatal testing, clinician visits, and any signs and symptoms for which they should be watching. The fetal deaths that have been reported after negative CSTs are often attributed to congenital malformations, placental abruption, and poor glucose control in women with diabetes; counseling for patients at risk should be appropriate.

#### **PATIENT EDUCATION GUIDES**

See patient education and consent forms available online at www. expertconsult.com.

# **CPT/BILLING CODES**

59020 Fetal contraction stress test

59025 Fetal nonstress test

If the patient has a diagnosis in addition to normal pregnancy, counseling for FMC is coded with an E/M code. If there is no additional diagnosis (normal pregnancy), preventive medicine codes should be used.

#### **ICD-9-CM DIAGNOSTIC CODES**

- V22.0 Supervision of normal first pregnancy
- V22.1 Supervision of other normal pregnancy
- 642.03 Benign, essential hypertension complicating pregnancy, antepartum
- 642.43 Mild or unspecified preeclampsia, antepartum
- 642.53 Severe preeclampsia, antepartum
- 642.63 Eclampsia, antepartum

- 642.73 Preeclampsia or eclampsia superimposed on preexisting hypertension, antepartum
- 645.13 Post-term pregnancy, pregnancy over 40 completed weeks to 42 completed weeks, antepartum
- 645.23 Prolonged pregnancy, pregnancy which has advanced beyond 42 completed weeks, antepartum
- 646.23 Unspecified renal disease, without mention of hypertension, antepartum
- 646.33 Habitual aborter, antepartum
- 648.03 Diabetes mellitus, preexisting, antepartum
- 648.83 Abnormal glucose tolerance (i.e., gestational diabetes), antepartum
- 656.43 Fetal demise, antepartum
- 656.53 Intrauterine growth restriction, antepartum
- 760.5 Maternal injury, fetus or newborn affected by maternal conditions

# EPISIOTOMY AND REPAIR OF THE PERINEUM

Montiel T. Rosenthal

Episiotomy is an intentional incision in the perineum used to facilitate the second stage of labor. Today, it is performed much less often in the United States than in previous years, when routine episiotomy was common. However, clinicians in Europe use it even less often, affirming that vaginal delivery is a natural process that does not necessarily benefit from intervention. Although use of an episiotomy may slightly decrease the risk for labial and anterior vaginal lacerations, avoidance of episiotomy leads to less maternal blood loss, less overall perineal trauma, less risk of disruption of the anal sphincter (third-degree extension) or rectal mucosa (fourthdegree extension), and less delay in the patient's resumption of sexual activity. Avoidance may also decrease risk of spontaneous lacerations with future deliveries. Eight studies that compared a restrictive policy of episiotomy with a policy of its routine use were reviewed for the Cochrane Database and found less posterior vaginal or perineal trauma with a restrictive policy and less overall need for suturing. Episiotomy therefore falls into the Cochrane category of "Forms of Care Likely to be Ineffective or Harmful," and it should not be performed routinely. However, for certain situations or indications, episiotomy may be unavoidable or extremely useful.

An episiotomy is performed to enlarge the vaginal outlet to facilitate delivery. Clinicians should be familiar with the anatomy of the vagina, introitus, and perineum (Fig. 166-1) before performing an episiotomy. In a midline or median episiotomy, the incision is made in a direct line posteriorly from the vagina, through the attachments of the bulbospongiosus muscle and the tendinous perineal body, and toward the anus. Mediolateral episiotomy directs the incision 45 degrees laterally from the midline at the base of the introitus (Fig. 166-2). Although performed more commonly in Europe, mediolateral episiotomy is rarely performed in the United States and is associated with more bleeding, a more difficult surgical repair, complicated healing, and a higher risk of postoperative pain, including dyspareunia. The only benefit to mediolateral episiotomy is a decreased risk of extension to a third- or fourth-degree tear. This chapter focuses on the midline or median episiotomy, although a modified "hockey stick" version of the midline and the mediolateral episiotomy is also discussed. In addition to the general risk factors for midline episiotomy, risk factors for third- or fourth-degree extensions include nulliparity, arrest of second-stage labor, persistent occiput posterior position, very short perineum, use of mid- or lowoutlet forceps, and use of local anesthetics.

# **INDICATIONS**

Any situation that prolongs the second stage of labor and thereby significantly endangers the life of the mother, the integrity of her perineum, or fetal well being could warrant episiotomy. The fact that episiotomy is a surgical procedure with attendant risks and potentially fatal complications has to be weighed against the need to shorten the second stage of labor by a few minutes. Current

obstetric literature suggests that episiotomy may be indicated when vaginal delivery is anticipated and one of the following maternal or fetal indications exists.

#### **Maternal Indications**

- Significant cardiac disease (e.g., mitral stenosis)
- Risk of significant perineal trauma (e.g., large infant, use of forceps or vacuum, imminent perineal rupture)

#### **Fetal Indications**

- Significant fetal distress in second stage
- Prematurity
- Breech or face presentation
- Shoulder dystocia
- Occiput posterior position (possible benefit)

Precipitous deliveries are associated with more perineal and pelvic injuries; therefore, a timely episiotomy is critical in this situation. For all other deliveries, less invasive maneuvers (e.g., perineal massage, warm perineal compresses, sitting for delivery, breathing, hands off until crowning, and slowing delivery of fetal head—delivering head between contractions and avoiding maternal pushing while the head is being delivered) may be helpful in alleviating second-stage complications or in reducing trauma. Again, recent evidence has suggested that episiotomy use should be restricted to instances where it is clearly indicated.

#### **CONTRAINDICATIONS**

# **Absolute**

The only absolute contraindication is patient refusal.

#### Relative

- Prior fourth-degree laceration or fourth-degree repair breakdown
- Severe scarring or malformation of perineum
- Extensive or large condylomata that may lead to frank hemorrhage if incised
- Prior or concurrent fistula
- Maternal disorders that impair healing such as autoimmune disorders, diabetes, or human immunodeficiency virus infection

## **EQUIPMENT**

 Sterile gown, gloves, drapes and any other equipment necessary for the clinician to follow universal blood and body fluid precautions.

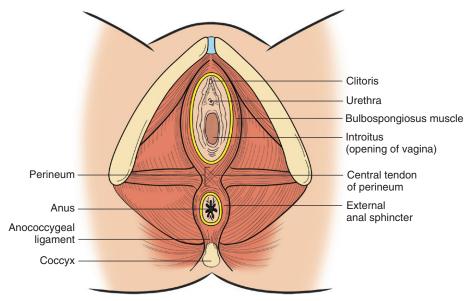

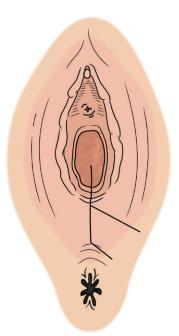

Figure 166-1 Anatomy of the vagina, introitus, and perineum.

- Povidone-iodine solution (or chlorhexidine if patient allergic to iodine).
- Blunt-tipped straight surgical scissors (e.g., Mayo scissors; a scalpel may also be used but the editors do not recommend this because it can cause significant injury to the mother, fetus, or clinician).
- Needle holder.
- Nontraumatic forceps.
- Vaginal retractor(s).
- Ring forceps.
- 4 × 4 sterile gauze sponges.
- 2-0 or 3-0 polyglycolic braided absorbable sutures (e.g., Vicryl, Dexon, Polysorb; preferred over chromic, which is associated with an increased risk of episiotomy breakdown and more discomfort during the first 3 days of healing; however, polyglycolic

**Figure 166-2** "Hockey stick" extension of midline episiotomy versus mediolateral episiotomy.

- sutures may more frequently cause local irritation and work themselves to the skin surface or fail to heal and have to be removed weeks later) on a large, curved cutting or tapered-point needle. Rapidly absorbable versions of polyglycolic sutures are now also available and may decrease the need for suture removal within the first 3 months after episiotomy repair.
- Allis clamps (especially for third- and fourth-degree extension repairs).
- 4-0 or 5-0 polyglycolic suture on smaller curved needle (for fourth-degree extension repairs).

**NOTE:** If effective regional (e.g., epidural, pudendal) anesthesia is not in place, a 10-mL syringe with a 1½-inch, 27-gauge needle should be available to locally infiltrate the anesthetic of preference (usually 10 mL 1% lidocaine *without* epinephrine; use ≤30 mL lidocaine).

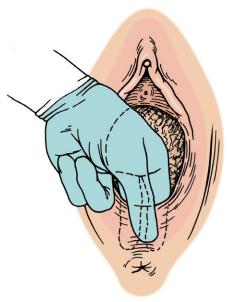

# PREPROCEDURE PATIENT EDUCATION

Discuss potential risks and possible benefits of an episiotomy with the patient (and partner) during prenatal care, *before* an emergent moment of need when neither the clinician nor the patient is in an optimal situation for exchange of information. Ideally, the patient's desires are part of a birth plan, and this should be discussed and written well before the pregnancy is at term. (See also Chapter 3, Epidural Anesthesia and Analgesia, Chapter 174, Pudendal Anesthesia, and Chapter 177, Vaginal Delivery, for examples.)

# **TECHNIQUE**

In the second stage of labor, as the fetal cranium begins to distend the maternal perineum, if time permits, effort should be directed toward assisting with the natural thinning of the perineum and dilation of the introitus (Fig. 166-3). These efforts should include applying warm compresses and placing tension on the perineum and gently stretching it from inside the introitus with the index and middle fingers. Labeling posterior as the 6 o'clock direction, rotate these fingers, under gentle tension (directed outwardly), from about the 4 o'clock to the 8 o'clock positions. Gentle exterior massage with the thumb or other hand at the same time, in this same location, may also help with thinning of the perineum.

The decision for episiotomy is usually made after the fetal cranium (not just the caput) distends the introitus. Waiting until

**Figure 166-3** Palpating and attempting to stretch and thin the perineum before episiotomy.

a minimum of 3 to 4 cm of the fetal scalp diameter is visible and delivery is imminent will prevent excessive blood loss. If the indication for episiotomy is for a forceps or vacuum delivery, most clinicians perform the episiotomy after application of the blades or vacuum device. Until this time, massaging the perineum, as described previously, may not only minimize bleeding but may provide some anesthesia by placing pressure on the local nerve endings. As the head further distends the introitus, an episiotomy may be needed if it appears that the head will not be deliverable without an episiotomy or that there will be so much tension on the perineum that it will tear (i.e., imminent rupture). An episiotomy may also be necessary for one of the other indications. If the patient is in stirrups, make sure the legs are not separated too widely or one leg placed higher than the other; this may produce excess tension on the perineum, resulting in an extension of the episiotomy into a third- or fourth-degree laceration. When performing this procedure, the clinician should follow universal blood and body fluid precautions.

- 1. With the palm of the clinician's nondominant hand facing outward, the index and middle fingers are inserted between the fetal scalp (or presenting part) and the maternal perineum, directed toward the maternal anus (toward the 6 o'clock position). The thumb should be placed on the exterior perineum. The thumb and fingers serve two functions: to protect the fetus and to palpate the anal sphincter as a reminder of its location for the clinician. The thumb defines the bottom of the episiotomy (see Fig. 166-3).
- 2. Check for adequate anesthesia by gently scratching the perineum with tissue forceps. If there is no anal "wink" reflex (i.e., sphincter contraction) with this scratching, it suggests adequate anesthesia. Further confirm anesthesia by gently pinching the perineum with the tissue forceps or an Allis clamp. Even epidural anesthesia or a pudendal block is not always effective, so be prepared to locally anesthetize the midline of both the perineum (for a median episiotomy) and the floor of the vagina. The middle and index fingers should be in place between the fetus and the perineum/floor of the vagina to avoid fetal injection with anesthetic.
- 3. Insert the blunt blade of the scissors inside the introitus to cut parallel to and between the fingers. Make the incision downward after bringing the other blade of the scissors flat against the skin on the outside of the perineum (Fig. 166-4). Again, take care to

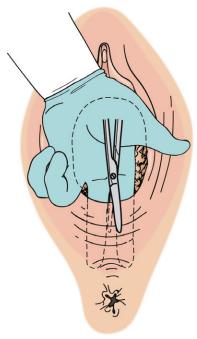

Figure 166-4 Performing the midline episiotomy.

protect the fetal presenting part. After the incision has passed the fetus, avoid cutting the external sphincter of the anus by keeping pressure posteriorly just above the fullness of the anus. Under direct visualization, extend the incision up the vaginal mucosa an additional 2 to 4 cm, through the hymenal ring, to release tension and prevent tearing. The introitus should readily open after making the episiotomy and delivery should proceed expeditiously to minimize blood loss.

In the patient with a very short perineum (especially if nulliparous or with prolonged second stage of labor, or the fetus is in the occiput posterior position), consider performing a variant of the median episiotomy, the "hockey stick" episiotomy (see Fig. 166-2). To form the hockey stick, as the midline incision is being made and before it reaches the anus, extend it laterally 1 to 2 cm. That way, if the incision extends further by tearing, it should naturally follow the "L" shape and avoid the anal sphincter. Another option is a mediolateral episiotomy (see Fig. 166-2). The incision is directed at a 45-degree angle to the midline of the posterior fourchette, from the hymenal ring toward the ischial tuberosity. The mediolateral episiotomy is usually made on the same side of the patient as the handedness of the clinician (e.g., right side of patient at about the 7 o'clock position for a righthanded clinician). The length of the incision is not as critical for a midline incision; however, the longer the incision, the more extensive the repair.

# Repair

- 1. Repair the episiotomy after the third stage of labor. This avoids disturbing the episiotomy repair with the delivery of the placenta. (If the episiotomy repair has already been completed, the sutures could become disrupted with delivery of the placenta, especially if a manual extraction is necessary. If the episiotomy is in the process of being repaired, delivery of the placenta often obscures the field with blood.) Again, the clinician should follow universal blood and body fluid precautions.
- Check again for adequate anesthesia by gently scratching the perineum, and if there is no anal "wink" reflex, by gently pinching the perineum with tissue forceps. If not already done, a pudendal block (see Chapter 174, Pudendal Anesthesia) can

- again be considered, especially if a third- or fourth-degree extension needs to be repaired. Check patients with an epidural in the same manner; additional local anesthesia may be helpful during repair.
- 3. A digital rectal examination should be performed after every delivery. After donning a clean glove and lubricating a finger with antiseptic solution, palpate the distal 6 cm of the rectal mucosa. The gloved finger should not be visible in the vaginal wound. Such a tear or "buttonhole," usually located superior to the sphincter, could later produce a rectovaginal fistula if left unrepaired. Determine whether the sphincter has sufficient "bulk" remaining (i.e., produces the sensation of a small doughnut being palpated). In the absence of this sensation, evaluate closely for a third-degree extension. Carefully examine the remainder of the lower urogenital tract for lacerations not contiguous with the episiotomy, repairing those that need it.

# Repair of Third- and Fourth-Degree Extensions (Tears)

1. If the rectal mucosa is no longer intact (fourth-degree extension), it must be repaired to prevent fistula formation. Reapproximate the submucosa and muscularis with 4-0 or 5-0 polyglycolic stitches (Fig. 166-5A). Use running or interrupted stitches placed 3 to 5 mm apart. (These are basically subcuticular stitches, but unlike subcuticular stitches placed in skin, these are placed from the other side—the back side—of the mucosa.) Reapproximating the submucosa and muscularis in this manner should invert the mucosa back into the lumen (Fig. 166-5B). Doing so will eliminate the risk of sequestering rectal mucosa in overlying tissue. Sutures should begin just above the apex of the laceration and proceed distally.

**NOTE:** If the apex of the laceration is not visible, an interrupted suture can be placed as close as possible to the apex and used to apply gentle traction toward the clinician, bringing the apex of the wound into view. This suture can later be removed. (A similar technique can be applied to *any* vaginal or even a cervical laceration when there is difficulty visualizing the apex.)

The musculature of the anal canal, including the anal sphincters, basically consists of two tubes, one inside the other. The inner cylinder, closest to the rectal mucosa, contains the internal anal sphincter, which consists of smooth muscle under involuntary control and provides the resting tone noted when performing a digital rectal examination. This cylinder, in turn, is surrounded by the thicker cylinder containing the external anal sphincter, which consists of skeletal muscle under voluntary control and can be used to squeeze the clinician's finger when a digital rectal examination is being performed.

- 2. After reapproximation of the mucosa, a second layer of running or interrupted 3-0 polyglycolic sutures should be placed to provide a reinforcing layer of fascia over the stitches in the submucosa. This layer should also close the torn ends of the internal anal sphincter, a roughly 2.5-cm-long (the most distal 2.5 cm of the anal canal) fibrous layer lying between the rectal mucosa and the external anal sphincter. It is identified as a white, glistening, fibrous structure that may have retracted laterally and need to be retrieved with an Allis clamp for repair. These sutures should give the wound additional strength, again decreasing the chance for fistula formation.
- 3. The external anal sphincter (third-degree extension) is then repaired by using three or four interrupted stitches. Suturing the sphincter muscle alone will not provide sufficient strength to hold until healing is complete, so the fibrous sphincter sheath (fascia) must also be reapproximated. It is identified as a tenacious white sheath, often retracted further laterally than the muscle edges. Search for the sheath on the posterior, inferior (caudal), superior (cephalic), and anterior aspects of the muscle. Again, lateral probing and fixation with an Allis clamp may be necessary.

4. Several techniques are described in the literature for external anal sphincter repair. Four simple sutures (Fig. 166-5C–I) can be placed in the posterior, superior (cephalic), inferior (caudal), and anterior portions of the muscle and the adjacent aspects of the torn sphincter sheath for an end-to-end repair. (Some experts place the posterior and caudal sutures first and then tie them last.)

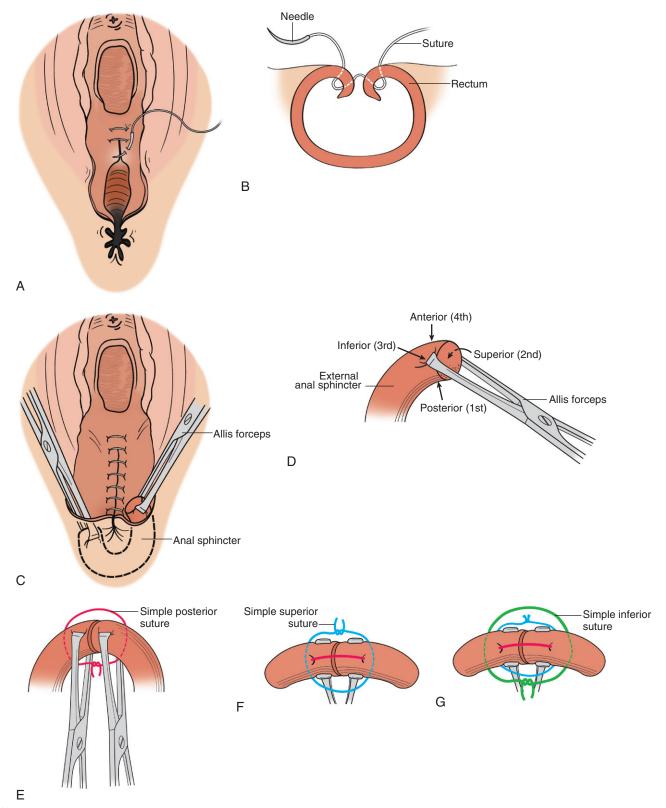

Alternatively, the ends of the sphincter may be pulled to overlap and sutured with three sutures. (Although the overlapping-type repair was initially thought to provide superior results, randomized trials comparing it with traditional end-to-end repair have failed to demonstrate superior anatomic or functional results.) Another method of end-to-end repair is to merely place two large transfixion sutures in the posterior and anterior aspects of the external sphincter. Usually it is easier to place the posterior transfixion suture first, followed by the anterior suture. These large transfixion sutures should also traverse the superior (cephalic) and inferior (caudal) sheaths in both locations (Fig. 166-5]).

 On completion, a repeat rectal examination should confirm adequate sphincter reapproximation and adequate "bulk"/ support. Examination glove should be discarded after rectal examination.

#### Repair of the Episiotomy

- 1. After any injury to the rectal mucosa and anal sphincters has been repaired, carefully examine the wound. Use 2-0 or 3-0 polyglycolic suture to place a stitch above the apex on the vaginal incision. Tie there, and then run it down to the introitus and reapproximate the hymenal ring (Fig. 166-6). It is critical that these stitches provide hemostasis, close all dead space, and not enter the rectum. Although some clinicians use a subcuticular running stitch for this reapproximation, it seems that simple stitches would be more effective at providing hemostasis and closing the dead space. One way to avoid entering the rectum is to take wide bites laterally on each side and then to bring the needle out at the base of the incision, ensuring that it does not go as deep as the rectum (merely piercing the rectum with a needle increases the risk of rectovaginal fistula). Either locked or unlocked sutures may be used, although the literature suggests that unlocked sutures are associated with less pain. If locked sutures are used, take care to avoid too much tension, which might cause tissue ischemia and necrosis.
- 2. At this point, two techniques are available, either continuing with the current suture to close the perineum for the one-suture technique (Fig. 166-7), or using an additional suture for the twosuture technique (Fig. 166-8). If the one-suture technique is chosen, after approximating the hymenal ring, the needle is buried beneath the hymenal ring to exit at the apex/top of the perineal wound. From there, running stitches are placed in the deep perineal tissue, roughly approximating the perineum (or at least taking the tension off the eventual subcuticular stitch) while proceeding to the most posterior aspect/bottom of the wound. After the deep perineal tissue has been reapproximated and the posterior aspect of the wound reached, the suture is redirected to become a running subcuticular stitch and used to close the skin of the perineum. The suture is run back up the perineum, and then the needle is again buried beneath the hymenal ring to exit through the already sutured incision in the vaginal mucosa. One final stitch is placed beneath the incision in the vaginal mucosa, to hide or invert it, a knot tied, and any remaining suture cut.

**NOTE:** Deep placement of the perineal subcuticular stitches (but leaving the perineal wound gaping only 2 to 3 mm) significantly decreases itching during healing with no loss of cosmesis or function. Also, avoid interrupted transcutaneous sutures when closing the perineum because they are associated with more pain in the immediate postpartum period compared with continuous subcuticular sutures.

**Figure 166-5** Repair of fourth-degree extension of a midline episiotomy. **A,** The rectal mucosa is repaired using interrupted submucosal stitches. **B,** Cross-sectional view of rectal laceration closure, inverting mucosa. **C,** The sphincter is retrieved with Allis forceps. **D,** Right edge of external anal sphincter from perineal view with order of placement of sutures. **E,** Placement of simple posterior suture, perineal view. **F,** Placement of simple superior (cephalic) suture, anterior view. **G,** Placement of simple inferior (caudal) suture, anterior view.

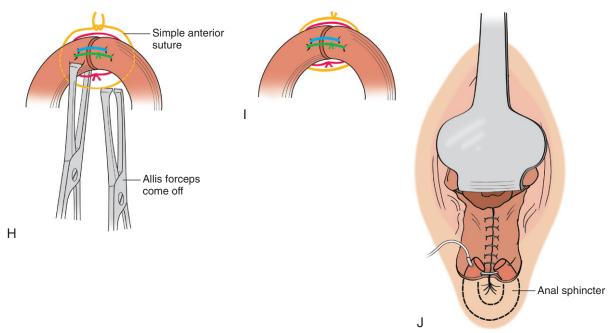

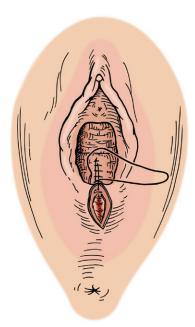

Figure 166-5, cont. H, Placement of simple anterior suture with removal of Allis clamps (perineal view). I, Complete closure of external anal sphincter (perineal view). I, Alternative technique of reapproximating external anal sphincter using two large transfixion sutures.

3. If the two-suture technique is used, after the hymenal ring is approximated with the first suture, the needle is buried beneath the hymenal ring to exit into the perineal wound. The needle is then laid aside or tagged with a hemostat to keep it out of the wound and ready for later use. With the second suture, a crown stitch is placed to carefully reapproximate the perineum where the bilateral bulbospongiosus (formerly known as bulbocavernosus) muscles merge (see Fig. 166-6B). Then, either interrupted or running sutures can be placed to close the perineum from the apex/top to the posterior/bottom of the wound. If a running

**Figure 166-6** Closure of the vaginal mucosa. The first stitch is placed above the apex of the wound and tied. This stitch is then usually continued as a simple or locked running stitch down to the introitus. The hymenal ring has been reapproximated and the needle is then taken to the depth of the perineum.

suture is used, after the deep perineal tissue has been reapproximated, the suture can then be redirected as a subcuticular stitch and run back up to close the skin of the perineum. At that point, when the first suture is reached, both needles are removed and the sutures tied together into an inverted knot. Alternatively, if interrupted sutures are used to repair the deep perineal tissue (see Fig. 166-8), the suture tagged after reapproximating the hymenal ring can then be used for a running subcuticular stitch to close the skin of the perineum.

- To repair a hockey stick extension, merely follow the incision with the subcuticular suture. Figure 166-9 diagrams the repair of a mediolateral episiotomy.
- 5. Once repair is complete, perform a final rectovaginal examination. Verify again that the rectal mucosa is intact and is not obstructed by suture, and that no gauze sponges or instruments remain in either the rectum or the vagina. Immediate correction, by removal of the existing repair and repeating the procedure with care, is imperative to minimize the risk of infection and fistula formation.

Figure 166-10 provides a flowchart that summarizes the episiotomy and repair technique.

#### **COMPLICATIONS**

- Blood volume loss is reported to be approximately 300 mL from an uncomplicated median episiotomy, but easily may be more if there is an unexpected delay in delivery or repair. Observe the patient carefully and treat proactively, especially if other conditions threaten to compromise the patient's blood volume (e.g., intravascular hypovolemia resulting from other blood loss or preeclampsia).
- Hematoma formation with acute swelling and pain is unusual but not rare. In addition to large vulvar hematomas, paravaginal and ischiorectal hematomas can occur. If present, a hematoma may need to be opened immediately. The bleeding must then be arrested and the space either closed or drained to prevent recurrence.
- Infection is probably the most serious threat to episiotomy recovery. A range of wound infections is possible, from a minor

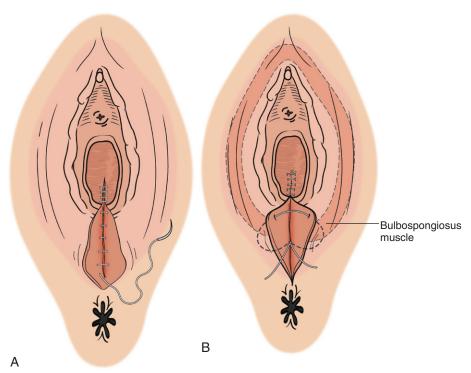

Figure 166-7 A, Repair of the vaginal mucosa has been completed with locked stitches. The hymenal ring and perineal body have been reapproximated and a deep running layer of perineal sutures has been placed, using the same suture. Finishing the perineal closure would entail running the subcuticular stitches back to the introitus. B, Alternative closure of deep perineum after running vaginal suture. The crown stitch approximates the perineal body, where the fibers of the bulbospongiosus muscles join from either side. (Dotted line indicates placement of suture out of view of the person doing the repair.)

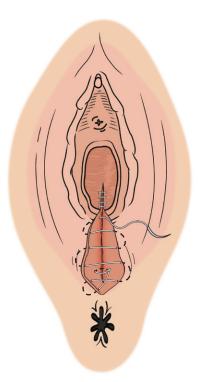

Figure 166-8 Two-suture technique of closing the deep perineal space. The second suture is used for deep interrupted stitches. The perineal skin is closed with a subcuticular stitch using either the second suture or the remaining first suture from the vaginal repair. (Dotted line indicates placement of subcuticular suture.)

superficial exudative wound infection to a life-threatening septic hematoma or necrotizing fasciitis. Maternal fever and unusual pain or swelling in the perineum must be evaluated thoroughly to rule out serious infection.

- Incontinence of stool or urine and flatus are possible complications of episiotomy, especially when associated with extensions.
- Rectovaginal and urogenital fistulas (vesicovaginal, vesicocervicovaginal, urethrovaginal, and ureterovaginal) may occur from either direct trauma (hence the importance of careful examination of the entire lower genital tract) or from infection or necrosis associated with suturing. Incontinence of either feces or urine starting 10 or more days after delivery should alert the clinician to the possibility of these complications.
- Pelvic relaxation and poor perineal tone, once thought to be minimized by performing an episiotomy, may actually be exacerbated by the procedure. Although not life-threatening, they may lead to a lifetime of misery and disability.
- Local pain or wound breakdown and dyspareunia are usually selflimited complications. Bartholin's duct cysts, inclusion cysts, and endometriosis at the wound site are rarely encountered but may require surgical repair.
- In addition to maternal complications, episiotomies place a nearby patient in jeopardy: the fetus. Fetal complications may range from injecting the scalp with anesthetic, producing lidocaine toxicity, to minimal abrasions, to rare but significant lacerations on the presenting part (e.g., eyelid lacerations and even castration of a male breech infant).

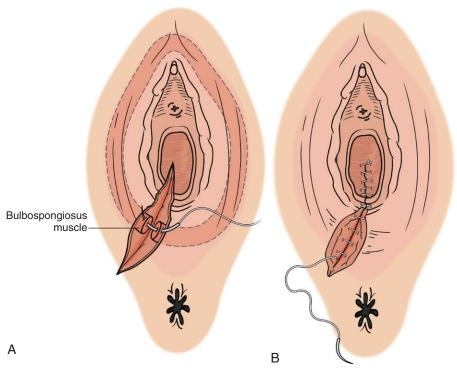

Figure 166-9 Repair of a mediolateral episiotomy. A, Similar to placing a crown stitch, the bulbospongiosus muscle is first approximated. B, The remainder of the episiotomy is repaired in a manner similar to a midline episiotomy, using either a one- or two-suture technique.

# POSTPROCEDURE MANAGEMENT AND PATIENT EDUCATION

After delivery, patients with sutures are less comfortable than patients without sutures, and women with episiotomies may experience more pain than women with minor lacerations. Many women will desire analgesia, and nonsteroidal anti-inflammatory drugs (e.g., ibuprofen) are increasingly used instead of acetaminophen with codeine. Codeine can be constipating, which is especially problematic among women after a third- or fourth-degree repair. Stool softeners may decrease pain with defecation as well as the risk of episiotomy disruption, especially after third- or fourth-degree extensions. The application of ice packs to the perineum the first 24 hours after delivery is efficacious for reducing swelling and postpartum pain, whereas warm sitz baths can provide comfort beyond the immediate postpartum period. Alternatively, adding ice cubes to a lukewarm sitz bath and soaking for 20 to 30 minutes may be preferred by some patients for pain relief. Potential complications must be discussed so that she is aware of the signs and symptoms for which she must immediately contact the clinician, especially bleeding, fever, or severe or persistent pain. Patients should also know that if a suture works its way to the surface, they can return to the clinician for removal.

# **CPT/BILLING CODES**

- 59300 Episiotomy or vaginal repair by other than the attending physician
- 59400 Routine obstetric care, including antepartum care, vaginal delivery (with or without episiotomy, and/or forceps) and postpartum care
- 59409 Vaginal delivery only (with or without episiotomy and/or forceps)

#### **ICD-9-CM DIAGNOSTIC CODES**

650 Normal delivery, requiring minimal or no assistance, with or without episiotomy, without fetal manipulation or instrumentation (forceps) of a spontaneous, cephalic, vaginal, full-term, single, live-born infant

The fifth digit (X) is required for codes 660 to 669 to denote the following:

- 0 Unspecified
- 1 Delivered, with or without mention of antepartum condition
- 2 Delivered, with mention of postpartum complication
- 3 Antepartum condition or complication
- 4 Postpartum condition or complication

The following codes are related to deliveries with forceps or vacuum:

- 659.7X Abnormality in fetal heart rate or rhythm
- 662.2X Prolonged second stage of labor

The following codes are related to episiotomy and episiotomy repair, and for repair of low vaginal lacerations:

- 664.0X First-degree perineal laceration
- 664.1X Second-degree perineal laceration
- 664.2X Third-degree perineal laceration
- 664.3X Fourth-degree perineal laceration
- 664.4X Unspecified perineal laceration

#### **ACKNOWLEDGMENT**

The editors wish to recognize the many contributions by Donald N. Marquardt, MD, PhD, to this chapter in the previous two editions of this text.

# EXTERNAL CEPHALIC VERSION

Andrew S. Coco

In about 4% of term pregnancies, the fetus is in the breech position. Because the risk of complications with vaginal breech delivery is generally considered high, almost 90% of these fetuses are delivered by cesarean section without a trial of labor. Practiced since the time of Aristotle, external cephalic version (ECV) is a procedure that externally rotates the fetus from a breech presentation to a vertex presentation. Trials of ECV conducted over the past 25 years demonstrate an extremely strong safety record, a success rate of about 60%, and factors predictive of success and failure (Box 167-1). As a result of these studies, as well as the widespread availability of ultrasonography, electronic fetal monitoring, and effective tocolytic agents, ECV has made a resurgence. In addition to reducing cost and being safe and effective, the manual skills to perform ECV are easily acquired. Despite these favorable features, ECV is still underused. In fact, breech presentation is the third most frequent indication for cesarean section (after labor dystocia and repeat cesarean). and it accounts for 12% of the cesarean sections in the United States. Routine use of ECV could substantially reduce the rate of cesarean section, even in patients undergoing vaginal birth after cesarean (VBAC; however, see section on Relative Contraindications). ECV can be performed in basically any setting that has an ultrasonography machine and an experienced clinician (comfortable with ultrasonography and ECV). Clinicians must also be equipped and prepared for cesarean section if the need for an immediate delivery arises.

## **INDICATIONS**

- Low-risk gestation at 36 weeks or more, by good dating criteria (at 36 weeks, likelihood of spontaneous version is low; alternatively, at 36 weeks, complications of immediate, iatrogenic, even preterm delivery are not severe).
- The type of breech (e.g., frank, complete, footling) is not a factor
  in determining suitability. Women with a fetus in transverse lie
  are also excellent candidates, as are those who are attempting
  VBAC (however, see section on Relative Contraindications).

**NOTE:** To perform ECV, it is preferable that the diagnosis of breech be made before the patient is in active labor! The further the breech is engaged in the pelvis, the more difficult the ECV; therefore the clinician should screen for breech, at least with Leopold's maneuvers, in every pregnancy near term.

#### **CONTRAINDICATIONS**

### **Absolute**

- Indications for cesarean delivery aside from fetal presentation (e.g., placenta previa)
- Major uterine or fetal anomaly
- Nonreassuring fetal monitoring pattern
- Multiple gestation

- Abruptio placentae
- Ruptured membranes

#### Relative

- Suspected intrauterine growth restriction
- Decreased amniotic fluid volume
- Maternal cardiac disease
- Maternal hypertension
- Previous cesarean delivery (in small studies, ECV was not associated with uterine rupture in patients with previous cesarean or VBAC; however, repeat cesarean is generally a safe operation)
- Maternal obesity

#### **EQUIPMENT AND SUPPLIES**

- Intravenous catheter with heparin lock
- Blood-drawing equipment for a complete blood count and blood type and screen
- Syringe with 0.25 mg of terbutaline (Brethine)

# Box 167-1. Factors Predictive of Successful and Failed External Cephalic Version

#### Factors Predictive of Successful Version

Increasing parity (most consistent factor in studies)
Normal amount of amniotic fluid (may be linear correlation
between success rate of ECV and AFI, i.e., higher success
rate with increasing AFI)

Fetal presentation (success rate with transverse lie approaches 90%)

Unengaged fetal part

Earlier attempts at ECV (increase success rate, but also increase risk of spontaneous reversion to breech)

#### Factors Predictive of Failed Version

Engaged fetal presenting part\*
Difficulty palpating the fetal head\*
Uterus tense to palpation\*
Maternal obesity
Cervical dilation
Anterior placenta
Anterior or posterior positioning of fetal spine
Descent of breech into pelvis
Decreased AFI

AFI, amniotic fluid index; ECV, external cephalic version. \*The success rate is >90% if none of the factors marked by an asterisk is present and <20% if two of these factors are present. There have been no successful ECVs when all three factors are present.

- Fetal heart rate monitor
- Examination table with Trendelenburg's position
- Ultrasonography machine
- Ultrasonic gel
- Towels
- Sterile gloves and lubricant (if vaginal examination is required)
- Syringe of Rh<sub>0</sub> (D) immune globulin (RhoGAM) for Rh-negative patients

#### PREPROCEDURE PATIENT EDUCATION

Usually the patient is examined and counseled in one clinic visit about risks, benefits, and alternatives to ECV (see the sample patient education form online at www.expertconsult.com) and returns for ECV at another visit. This delineation allows time for both the patient and her partner to make an informed decision about ECV. At the ECV visit, the patient should bring a signed consent form (see the sample patient education form online at www. expertconsult.com). The procedure should be scheduled as close to (but not before) 36 weeks' gestational age as possible to maximize the chances of success while, it is hoped, avoiding a preterm birth. Before 36 weeks, although there is a high success rate for ECV, fetuses are more likely to spontaneously revert to breech. The patient should be instructed not to eat a heavy meal during the 3 hours before ECV. The clinician should also reassure the patient that ECV causes only minimal discomfort. The results of studies are mixed regarding use of conduction analgesia. Some studies show an increased success rate with epidural analgesia, whereas other studies showed no benefit with use of spinal analgesia. This has led the American College of Obstetricians and Gynecologists (2000) to conclude that there is insignificant evidence to recommend routine use of conduction analgesia with ECV.

# **TECHNIQUE**

- Perform an ultrasonographic examination to confirm a singleton in breech or transverse presentation, determine the amniotic fluid index, note the placental location, and rule out uterine malformations or congenital anomalies. The patient should empty her bladder after the ultrasonographic examination.
- 2. Perform a nonstress test to confirm a reassuring fetal heart rate tracing.
- 3. Draw blood for a complete blood count; type and screen. Establish intravenous access.
- 4. Administer a tocolytic agent, such as terbutaline (Brethine), subcutaneously about 15 minutes before the procedure. (This is

- optional because studies show conflicting efficacy. However, some type of relaxation technique should be used. One study in the literature demonstrates efficacy of hypnosis for spontaneous version.)
- 5. Place the patient in slight Trendelenburg's position to facilitate disengagement and mobility of the breech. Liberally coat the abdomen with ultrasonic gel to decrease friction and lessen the chances of an overly vigorous manipulation.
- 6. One or two persons may perform ECV. Determine the degree of pelvic engagement of the breech and perform gentle disengagement, if possible. Sometimes this requires a second operator to attempt vaginal disengagement. Successful disengagement is usually the key factor in achieving success. After the buttocks are elevated out of the pelvis and displaced laterally, the clinician(s) grasps each fetal pole in a hand.

**NOTE:** The breech (i.e., buttocks) is what is actually manipulated during the maneuver. The head is merely guided gently toward the pelvis while the breech is actively moved cephalad.

- 7. Attempt either the classic forward roll or the back flip. Most clinicians tend to try the forward roll first (Fig. 167-1). However, some base their preference on whether the fetus is mostly on one side of the uterus (e.g., fetal head and spine are on the same side of the maternal midline) or not. A forward roll is chosen if the fetal head and spine are on different sides of the maternal midline, and a back flip (Fig. 167-2) is chosen if they are on the same side. Emphasis should be on gentle persuasion of the fetus, as opposed to forceful movements.
- 8. In most cases, if it is going to occur at all, success is attained quite easily. If the first attempt is unsuccessful, a second attempt is made in the opposite direction. An attempted version should be discontinued for significant maternal discomfort or a persistently abnormal fetal heart rate. After two failed attempts, if another attempt is to be made, it should be rescheduled.
- 9. It is important to monitor the fetal heart rate with the ultrasonography probe for fetal distress (e.g., bradycardia) immediately after all attempts. If persistent fetal bradycardia is noted after a successful version, return the infant to its previous breech presentation in hopes of reducing umbilical cord compression. Ultrasonography is also used after all attempts to confirm success or failure.
- Regardless of success or failure, perform a nonstress test after the procedure to exclude fetal heart rate abnormalities.
- 11. Administer RhoGAM after the procedure to all Rh-negative patients because of a 4.1% risk of fetomaternal blood exchange.

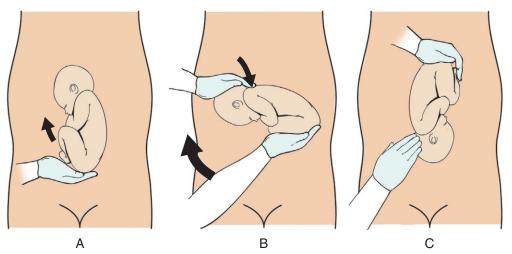

Figure 167-1 External cephalic version using the classic forward roll. A, The breech is mobilized. A second person is sometimes needed to vaginally disengage the fetus. B and C, At the same time, the breech is gently pushed upward while the head is directed into the pelvis.

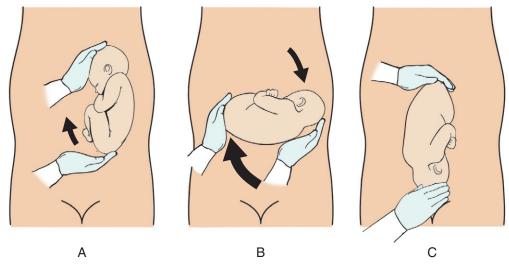

Figure 167-2 External cephalic version using the back flip. A, As with the forward roll, the breech is mobilized, possibly using a second person to vaginally disengage the fetus. B and C, At the same time, the breech is gently pushed upward while the head is directed into the pelvis.

12. If an attempt is unsuccessful and no evidence of fetal compromise is found, it is safe and cost effective to repeat ECV several days to 1 week later.

**NOTE:** ECV is easier to perform with multiparous mothers and when there is plenty of amniotic fluid. ECV may be worth considering, even in early labor, in multiparous women while en route to cesarean. It should never be performed under anesthesia unless the clinician is very experienced or is preparing for cesarean section. The technique should never be so forceful as to cause so much discomfort that anesthesia is necessary.

#### SAMPLE OPERATIVE REPORT

See sample operative report online at www.expertconsult.com.

#### **COMMON ERROR**

Attempting to turn the fetus before mobilizing the breech from the pelvis is the most common error.

# **COMPLICATIONS**

In general, ECV is very safe. When a protocol is used that includes fetal heart rate monitoring, ultrasonography, and ready access to operative delivery, the complication rate has ranged from about 1% to 2% since 1979. Most important, the literature provides overwhelmingly reassuring evidence against the risk of fetal death. Since 1980, only two fetal deaths have been reported with ECV. Both occurred when ECV was performed without the use of fetal heart rate monitoring or ultrasonography in preterm infants in Zimbabwe. In other words, there are no reports of fetal death when a protocol has been used similar to that outlined in this chapter.

- The risk of spontaneous reversion to a breech presentation after successful version is about 7%.
- Occasionally, the procedure needs to be discontinued because of significant or excessive maternal discomfort.
- There is a small risk of premature rupture of membranes or active labor within several days after the procedure. If the ECV was unsuccessful, either of these events could lead to a cesarean section for breech presentation, depending on patient and provider interest in an attempt at vaginal breech delivery.

- Transient, benign changes in fetal heart rate tracings are common (up to 39% in one study). There is a small risk of more worrisome changes, such as severe variable decelerations, late decelerations, or persistent bradycardia. These changes could signify placental abruption or umbilical cord entanglement and therefore necessitate an urgent cesarean section.
- Nonfatal fetomaternal hemorrhage occurs in about 4% of cases.
   A case of fetal brachial plexus injury has been reported.
- One maternal death has been reported due to amniotic fluid embolism. There is also risk of uterine rupture.
- After successful ECV, several reports suggest that the risk of cesarean delivery does not revert to institutional risk for vertex presentations. Dystocia, malpresentation, and nonreassuring heart rate patterns may be slightly more common after ECV.
- Authors of a systematic review of 44 studies involving 7377
  patients from 1990 until 2002 concluded in 2004 that ECV is a
  safe procedure for both the mother and fetus.

## POSTPROCEDURE MANAGEMENT

Follow-up visits and plans for a repeat attempt at ECV (in the event of an unsuccessful attempt), or a cesarean section when labor ensues are important to discuss with the patient.

#### POSTPROCEDURE PATIENT EDUCATION

- The clinician should discuss the postprocedure information on the sample patient education handout (see the sample patient education handout online at www.expertconsult.com), reemphasizing the major concerns.
- Clinicians should teach women who have undergone a successful ECV how to check their abdomen for reversion to breech, and women should do so daily. If the fetus has reverted, they should call or return to the clinic. One study has shown that training women to make regular self-assessments of the presenting part after successful ECV could improve the ultimate rate of vaginal delivery through the use of prompt, repeat ECV when reversion is detected before labor.
- Patients should call for any signs of premature rupture of membranes or labor. They should be instructed about the symptoms of both.

# FETAL SCALP ELECTRODE APPLICATION

Beth A. Choby

Fetal heart rate monitoring is the most common obstetric procedure in the United States, with approximately 85% of fetuses being assessed with internal or external monitoring during labor. Electronic fetal monitoring (EFM) became possible in the 1950s with Edward Hon's design of an electrode that directly attached to the fetus. EFM entered widespread clinical use in the late 1960s despite the fact that evidence supporting its benefit was nominal (i.e., limited to case reports and retrospective studies).

Intermittent auscultation and continuous EFM are both available for assessing fetal heart rate trends. To perform intermittent auscultation, a hand-held Doppler ultrasonography transducer is used at specific intervals during labor. However, this requires a one-to-one nurse-to-patient ratio and an explicit auscultation schedule; therefore, intermittent auscultation is both difficult and expensive to perform. Although the majority of professional maternity care societies believe that some type of fetal monitoring is needed during labor, no randomized, controlled trials have compared either intermittent auscultation or continuous EFM with no monitoring. Because continuous EFM is simpler and less expensive and provides more data, it has become the default method of monitoring on most labor units, especially in the United States.

Continuous EFM is available either through external or internal monitoring. With external monitoring, a cardiotocometer measuring fetal heart rate is attached across the maternal abdomen using a belt. Internal EFM technology makes use of a bipolar spiral electrode that attaches directly to the fetal scalp. An electrical circuit is created between the wire electrode that twists into the fetal scalp and the metal wing on the electrode. Vaginal fluids create a saline electrical bridge and close the circuit. The resulting voltage difference (fetal cardiac signal) is amplified and transferred to a cardiotocometer that calculates heart rate. The bipolar wires also connect to a reference electrode on the maternal thigh to minimize electrical interference.

Both internal and external EFM are hindered by poor intraobserver consistency and a high false-positive rate. Continuous EFM is usually performed with the patient in dorsal lithotomy position and likely contributes to dysfunctional labor. Widespread use of EFM is associated with higher rates of cesarean delivery, operative vaginal delivery, and litigation. Continuous EFM has limited ability to identify a truly hypoxic–ischemic fetus and fails to decrease rates of cerebral palsy. In a recent meta-analysis of 13 randomized, controlled trials, the only clinically significant benefit for routine continuous EFM was the prevention of neonatal seizures.

With older EFM technology, internal scalp electrodes provided more accurate information on fetal heart rate trends than external monitoring. Newer-generation equipment allows for better evaluation of beat-to-beat variability (short-term variability) using the external monitor. Scalp electrodes are less frequently used as a result of these improvements in technology. Because certain situations still necessitate the use of an internal monitor, understanding both the application and use of the fetal scalp electrode is important for maternity care providers.

**NOTE:** Discussion of the subtleties of the abnormal fetal heart rate tracing is beyond the scope of this chapter. The practitioner of maternal and fetal care is referred to any recent comprehensive obstetrics textbook for this information. The entire clinical picture, including stage of labor, concurrent medical problems, current medications, and availability of a physician to perform an operative delivery, should be considered when making management decisions.

#### **INDICATIONS**

Most healthy, low-risk pregnancies are safely monitored with intermittent auscultation or continuous external monitoring. Higher-risk pregnancies affected by maternal or fetal medical complications often require continuous monitoring. Although continuous external monitoring is usually adequate, the following situations warrant consideration of internal monitoring with a fetal scalp electrode (FSE):

- Ineffective external monitoring or inadequate fetal tracing as a result of
  - Maternal body habitus
  - Excessive maternal movement
  - Excessive fetal movement
- Inadequate staffing for provision of intermittent auscultation
- Nonreassuring fetal heart rate patterns
- Persistent fetal bradycardia (fetal heart rate [FHR] < 110 beats per minute [bpm])
- Persistent fetal tachycardia (FHR > 160 bpm)
- Decreased beat-to-beat variability on external monitoring
- Lack of FHR accelerations
- Moderate to severe variable decelerations
- Repetitive late decelerations

# **CONTRAINDICATIONS**

#### **Absolute**

- Nonreassuring fetal status mandating emergent delivery
- Nonvertex presentation
- Patient refusal/uncooperative patient
- Active maternal hepatitis C, human immunodeficiency virus (HIV), or transmissible blood infection
- Placenta previa
- Vasa previa

- Head not fully engaged in maternal pelvis (membranes may rupture when applying FSE; possibility of prolapsed cord cannot be excluded)
- Inadequate cervical dilation to allow safe placement of FSE

#### Relative

- Untreated group B Streptococcus (GBS) infection
- Imminent delivery (relative)

# **EQUIPMENT AND SUPPLIES**

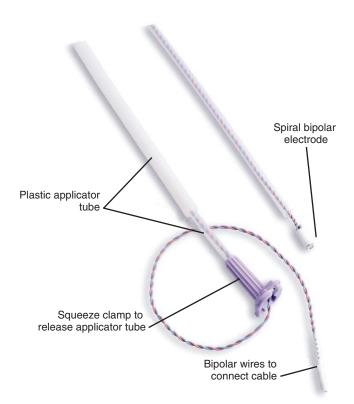

- Scalp electrode (FSE; Fig. 168-1)
- Fetal monitor
- Sterile gloves
- Connecting wires between FSE and electronic monitor
- Surgical lubricant or povidone–iodine solution

Scalp electrodes and fetal monitoring equipment are available on all labor units. Familiarity with locally available equipment is suggested.

#### **PRECAUTIONS**

- Vertex presentation
- Cervical dilation greater than 2 cm
- Ruptured membranes
- Head well engaged in maternal pelvis to decrease the risk of cord prolapse during FSE application

The fetal presentation, station, and position are determined from a sterile vaginal examination. If the placental location is unknown, bedside ultrasonography is helpful to rule out placenta previa and confirm vertex presentation. Rupturing the membranes (see Chapter 164, Amniotomy) makes applying an FSE easier, although it can be

**Figure 168-1** Fetal scalp electrode with applicator tube. (Courtesy of GE Healthcare, Waukesha, Wisc.)

applied through the amniotic sac to create a "slow leak" of amniotic fluid. Rupturing membranes when the head is not fully engaged (i.e., "floating" in uterus) can result in cord prolapse. When meconiumstained fluid is encountered, fetal well-being should be closely assessed using continuous monitoring or a biophysical profile.

# PREPROCEDURE PATIENT EDUCATION AND FORMS

Indications for FSE placement are discussed with the patient. Patient discomfort is generally minimal, and the procedure usually takes only a few minutes. Pain to the fetus is thought to be minimal. Showing the patient an FSE may help allay her concerns.

The patient lies in dorsal lithotomy position and the FSE is placed after a cervical examination to confirm fetal presentation. Fundal pressure from an assistant is helpful to reduce the risk of cord prolapse. Most hospitals do not require patients to sign specific operative consents for this procedure; obtaining verbal informed consent from the patient is prudent.

#### **TECHNIQUE**

The following steps are performed when applying an FSE:

- 1. Read the package insert accompanying the FSE.
- 2. Put sterile gloves on both hands.
- Confirm vertex presentation and assess for adequate cervical dilation (>2 cm).
- 4. Perform an amniotomy if membranes are intact and there are no contraindications (see Chapter 164, Amniotomy).
- 5. Ask an assistant to apply the adhesive pad (reference electrode) to the maternal thigh and connect the leads to the fetal electrocardiographic (ECG) monitor.
- 6. Holding the scalp electrode, free the tail wire to permit clockwise rotation of the electrode in the applicator tube.
- 7. Place the tip of applicator tube between the pads of the index and middle fingers of the hand used for vaginal examination.
- 8. Insert the fingers and applicator into the vagina and slide them toward the fetal vertex.

**NOTE:** Be careful to avoid the fetal fontanelles. The electrode should not be placed on or near the anterior or posterior fontanelle.

- 9. Place the electrode against the fetal skull. Turn the outer portion of the FSE clockwise approximately two times until a "pop" is felt. Applying the electrode during a contraction or with fundal pressure from an assistant makes placement easier and decreases the risk of cord prolapse.
- 10. Ensure that the scalp electrode tip is well anchored by applying gentle, external/outward traction on the electrode applicator (which is still attached to the wires of the FSE). If the FSE holds in place with this maneuver, it is likely well anchored. If the FSE pulls loose with this maneuver, a second attempt should be made to implant the FSE nearby. Before attempting to reimplant, the FSE should be turned counterclockwise twice in the applicator (i.e., to untwist the wires). Then, while applying the FSE with slightly more pressure against the fetal skull than last time, a reassuring "pop" should be felt with two more clockwise turns of the tip. If the clinician is unable to anchor the electrode after a second attempt, the next attempt should be made with a new FSE.
- 11. Palpate the area around the scalp electrode to check that it is not applied to the maternal cervix or vaginal walls. Also ensure that it is not connected on or around the anterior or posterior fontanelle.
- 12. Unwind the wires from the clamp located on the exterior end of the scalp electrode.

- 13. Gently squeeze the clamp and allow the applicator to slide over the wires and out of the vagina. If the FSE pulls loose with this maneuver, it was not well anchored and should be removed. The next attempt should be made with a new FSE.
- 14. Have the assistant connect the red and green FSE wires to the cable that attaches to the fetal monitor.
- 15. Switch the fetal monitor setup from Doppler to ECG.
- 16. Review the ECG tracing for nonreassuring signs, including persistent tachycardia/bradycardia, decreased variability, or decelerations (discussed in Chapter 165, Antepartum Fetal Monitoring). If severe decelerations are noted, check for umbilical cord prolapse immediately. If cord prolapse is noted, the vertex should be pushed up into the uterus while an emergent cesarean delivery is arranged.
- 17. Consider whether placing an intrauterine pressure catheter is necessary (see Chapter 171, Intrauterine Pressure Catheter Insertion).

#### SAMPLE OPERATIVE REPORT

A formal note detailing the indications for FSE placement and specifics of the procedure should be documented in the chart.

Procedure: Fetal Scalp Electrode placement for internal EFM Indication: Inability to perform external monitoring due to (circle one):

Maternal body habitus Maternal activity Fetal movement Poor external tracing

Other:

Procedure: Risks, benefits, and alternative options were discussed with the patient/family. The patient provided informed consent and agreed to proceed. A sterile vaginal exam was performed demonstrating vertex presentation, cervical dilation of \_\_\_\_\_ cm, and a well-engaged fetal head. The membranes were/were not artificially ruptured. The FSE was applied to the fetal scalp, avoiding the fetal fontanelles. The patient and fetus tolerated the procedure well and a reassuring tracing was noted after FSE placement.

#### **COMMON ERRORS**

- Incorrect placement of the FSE onto maternal tissue
- Placement of the FSE close to the maternal cervix
- Entanglement of the FSE in fetal hair without fetal scalp attachment
- FSE attachment on or close to the fetal fontanelles
- Puncture injury to operator's finger from an extended bipolar wire

Scalp electrodes inadvertently attached to the maternal cervix or vagina do not provide an ECG tracing when connected to the monitor. FSEs placed close to the maternal cervix create pronounced vertical spikes on the tracing secondary to "bumping" against the cervix. No ECG tracing is apparent if the electrode is tangled in the fetal hair. Scalp electrodes attached on or near a fontanelle or on locations other than the fetal scalp should be removed immediately. Keeping the electrode sheathed in the applicator until the fetal skull is palpated helps avoid an unintentional puncture injury to the person applying the FSE.

## **COMPLICATIONS**

- Fetal scalp abscess
- Meningitis, cerebrospinal fluid leak, or infection if an FSE is applied on a fontanelle

- Cephalohematoma or subcutaneous scalp emphysema if vacuum extraction is performed. The FSE should be removed before vacuum application. Depending on clinician experience, forceps may be preferred over vacuum-assisted delivery after FSE placement.
- Fetal trauma if FSE is incorrectly placed or applied in nonvertex positions: ocular injury in face presentation; scrotal, labial, or buttock lacerations with breech presentation
- Umbilical cord prolapse
- Increased risk of neonatal GBS sepsis if intrapartum antibiotic treatment is not given to mothers with GBS infection
- Puncture injury to the clinician applying the FSE

# POSTPROCEDURE MANAGEMENT AND PATIENT EDUCATION

Patients should be warned not to make sudden position changes or attempt to get out of bed without the hospital staff disconnecting the wire leads for the FSE. Internal monitoring generally limits patient mobility, although women may elect to sit in a rocking chair or on a birthing ball if close attention is paid to the wire leads.

# REMOVING THE FETAL SCALP ELECTRODE

#### Indications

- Impending delivery (fetal head crowning)
- Application of vacuum-assisted device
- Cesarean delivery
- Inadvertent electrode placement on maternal tissue or nonscalp fetal parts
- Signal interference because of proximity of electrode to cervix

#### **Technique**

- 1. Remove the electrode when the fetal skull is visible between contractions with the head on the perineum.
- 2. Cut the wire leads with scissors approximately 2 inches from the perineum.
- 3. Manually untwist the wires until they can be easily unwound.
- The electrode tip spins counterclockwise and unscrews from the fetal scalp. This usually happens as the wires are being untwisted.
- Electrodes occasionally become tangled in the fetal hair. In this situation scissors are helpful for FSE removal.
- 6. During precipitous deliveries, cut the wire leads close to the perineum to prevent the electrode from catching and pulling on the fetal scalp. The electrode is easily removed after delivery.

# **CPT/BILLING CODES**

A specific code does not exist for FSE placement.

- 59050 Fetal monitoring during labor by consulting physician (not attending physician) with written report; supervision and interpretation
- 59051 Fetal monitoring during labor by consulting physician (not attending physician) with written report; interpretation only
- 59400 Routine obstetric care including antepartum care, vaginal delivery with or without episiotomy, forceps, or both, and postpartum care
- 59409 Vaginal delivery only (with or without episiotomy, forceps, or both)
- 59410 Vaginal delivery including postpartum care (excluding antepartum care)
- 59610 Successful vaginal birth after previous cesarean (VBAC)

# **ICD-9-CM DIAGNOSTIC CODES**

- Fetal distress, acid-base imbalance, affecting management of pregnancy or delivery, antepartum complication
   Placental insufficiency affecting management of mother, antepartum complication
- 656.83 Meconium-stained fluid, affecting management of pregnancy or delivery, antepartum complication
- 656.83 Fetal distress, NOS, affecting management of pregnancy or delivery, antepartum complication
- 663.00 Umbilical cord prolapsed, antepartum
- 762.2 Placental insufficiency, affecting fetus or newborn
- 767.19 Cephalohematoma, because of birth injury
- 768.3 Fetal distress, liveborn, during labor and delivery
- 792.3 Meconium-stained amniotic fluid

# **ACKNOWLEDGMENT**

The editors wish to recognize the many contributions by Timothy J. Downs, MD, to this chapter in a previous edition of this text.

# FORCEPS- AND VACUUM-ASSISTED DELIVERIES

Carol Osborn • Jennifer Bell • Dale A. Patterson

Knowledge and experience with instrument-assisted (forceps or vacuum) delivery are important for all obstetrics providers managing the second stage of labor, particularly if there is an emergency, such as severe fetal or maternal compromise. In unexpected situations the knowledgeable use of an assisted delivery may be lifesaving and help reduce morbidity. Assisted deliveries are also a safe alternative to an operative delivery, as long as criteria and indications are followed. The incidence of assisted delivery is decreasing (especially forceps deliveries), in part because the incidence of cesarean delivery is increasing. Only 6% of all vaginal deliveries were assisted deliveries in the United States in 2002. The safe use of these procedures depends on understanding and clinically establishing the station and position of the vertex. A Cochrane review comparing forceps with vacuum found slightly more deliveries with vacuum, and fewer cesarean sections, less maternal trauma, and less general and regional anesthesia use with vacuum. However, the vacuum extractor was associated with an increase in neonatal cephalhematoma and retinal hemorrhages. Serious neonatal injury was uncommon with either form of assisted delivery or instrument.

# **CLASSIFICATION**

Because of difficulties in estimating engagement and in defining different stations, the American College of Obstetrics and Gynecology (ACOG) defined and reclassified instrumented deliveries. The intention of this reclassification is to improve the safety of assisted deliveries and is discussed in the following sections.

## **Outlet Forceps or Vacuum**

- Fetal skull has reached the pelvic floor.
- Fetal scalp is visible between contractions.
- Sagittal suture is in an anteroposterior diameter (i.e., occipitoanterior [OA], right occipitoanterior [ROA], left occipitoanterior [LOA], occipitoposterior [OP], right occipitoposterior [ROP], or left occipitoposterior [LOP]) that is less than 45 degrees from the midline.

# Low Forceps or Vacuum

- Leading edge of the vertex is at +2 or greater station.
- Fetal head at this station fills the hollow of the sacrum.
- Head is not on the pelvic floor.
- Rotations are less than 45 degrees.

# Midforceps or Vacuum

- Head is engaged.
- Vertex is higher than +2 station.
- Advisable only in emergency situations.

With the classification change, the term *high forceps* has been eliminated. High forceps describes application of the forceps before engagement of the vertex. This procedure has no place in modern obstetrics because of unacceptably high morbidity rates. Midinstrumentation is reserved for providers who are experienced with this application. If an obstetrics provider is uncomfortable with the evaluation or application of forceps, a cesarean section is likely a safer route of delivery.

Before any forceps or vacuum application proceeds, the position and station of the vertex presentation must be determined. First, fetal engagement is verified. By definition, engagement indicates the biparietal diameter has passed the plane of the inlet. Clinically the fetal skull is at or below the ischial spines (i.e., 0 station). Checking the amount of space between the fetal head and the symphysis gives an additional measurement of station (Fig. 169-1).

Two things that complicate the clinician's ability to ensure complete engagement and assess descent are (1) molding, which leads to overestimation of descent or station, and (2) asynclitism or OP presentation, which also leads to overestimation of station. To avoid this miscalculation, the clinician should always confirm that the fetal head fills the sacral hollow. When the vertex fills the sacral hollow there should not be room to admit the fingers of the examining hand.

Position can be difficult to determine, especially if the head has marked caput. The following method helps determine position:

- Anterior fontanelle is shaped like a cross or plus (+) and is usually larger than the posterior fontanelle.
- Posterior fontanelle is shaped like a Y.
- When in doubt, the clinician should find the fetal ears to determine position.

If the position and descent meet criteria for an outlet or low instrumentation, then the provider needs to consider whether to use forceps or a vacuum to assist the delivery. The pros and cons of forceps versus vacuum extraction are described in Box 169-1.

# **INDICATIONS**

# **Conditions Required for Instrumentation**

- Vertex presentation (As noted previously, instrumentation may also be required to deliver the head in breech presentation. However, vertex presentation is required for the usual suction and outlet or low forceps applications.)
- Complete cervical dilatation
- Ruptured membranes
- No known severe cephalopelvic disproportion
- If unsuccessful, willingness to abandon procedure and proceed to cesarean section
- Adequate anesthesia is established

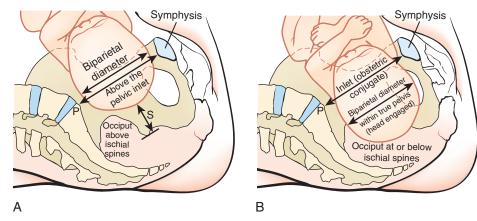

Figure 169-1 A, When the lowermost portion of the fetal head is above the ischial spines, the biparietal diameter of the head is not likely to have passed through the pelvic inlet and therefore is not engaged. B, When the lowermost portion of the fetal head is at or below the ischial spines, it is usually engaged. Exceptions occur when there is considerable molding, caput formation, or both. P, sacral promontory; S, ischial spine. (Modified from Cunningham FG, MacDonald P, Gant N, et al [eds]: William's Obstetrics, 19th ed. East Norwalk, Conn., Appleton & Lange, 1993.)

# **Maternal Indications for Instrument Delivery**

- Maternal exhaustion. This is associated with prolonged secondstage pushing. Maternal exhaustion is especially common in the nulliparous labor. The lack of a trained labor companion during the second stage is associated with a longer labor and increased use of instrumentation.
- Lack of maternal cooperation.
- Prolonged second stage or failure to progress. The average second stage is 50 minutes for primiparous patients and 20 minutes for multiparous patients. Regional anesthesia prolongs the second stage by inhibiting the maternal urge to push (Table 169-1).
- Medical conditions for which the strain of the second stage of labor would be deleterious. Examples include cardiac valvular disease, respiratory disease (e.g., active asthma), cerebrovascular disease, toxemia, and chronic hypertension.

# Maternal and Fetal Indications for Instrument Delivery

- Relative cephalopelvic disproportion.
- Malposition (OP or OT).

- Malpresentation (face or breech); use forceps only. For breech deliveries, forceps are often needed for the aftercoming head once the body has been delivered.
- Hemorrhage.
- Intrapartum infection.

# **Fetal Indications for Instrument Delivery**

- Nonreassuring fetal heart tracing
- Rapid deterioration of the tracing or any condition that makes it unsafe for the fetus
- Premature placental separation

# **CONTRAINDICATIONS**

# **Absolute**

- Fetal head not engaged
- Position of the head not determined (forceps)

# Relative

 History of a failed forceps or vacuum delivery with a macrosomic fetus

# Box 169-1. Forceps versus Vacuum Extraction

## Forceps

Pros

Higher rate of successful vaginal delivery Usually a more rapid delivery (e.g., for fetal distress)

Useful in breech (for the aftercoming head) and face presentations

Useful for rotations if clinician is experienced with these

Cons

Requires significant experience
Increased risk of neonatal craniofacial injuries
Increased risk of intracranial hemorrhage
Requires more maternal anesthesia
Associated with more considerated and

Associated with more cervical, vaginal, and perineal lacerations

## Vacuum

Pros

Easy to apply

Teaches the clinician to follow the pelvic curve

Allows autorotation from occipitoposterior and occipitotransverse positions Less force applied to the head

Requires less anesthesia

Results in fewer cervical, vaginal, and perineal lacerations

Easier to learn

Clinician can use if not completely sure of head position

Con:

Difficult to maintain vacuum if head is molded or infant has full head of hair Pull only with contractions, which increases time needed for successful delivery Associated with intracranial hemorrhage at a greater rate than spontaneous deliveries

Only useful in vertex presentations

Increased incidence of cephalhematomas and retinal hemorrhage

	TABLE 169-1 Limits of the Duration of the Second Stage of Labor before Intervention			
Parity	Without Regional Anesthetic	With Regional Anesthetic		
Nullipara Multipara	2 hr I hr	3 hr 2 hr		

- Suspected fetal coagulation defect
- Incomplete cervical dilatation (only exceptions are the urgent delivery of a second twin and a severely abnormal tracing without immediately available cesarean section)
- Delivery requiring excessive traction
- Prematurity (vacuum not recommended before 34 weeks' gestation because of increased risk of intracranial hemorrhage)
- Malpresentation (e.g., breech, face, brow, transverse lie)
- Prior scalp sampling (vacuum)
- Position of fetal head not precisely determined in vertex presentation (vacuum)

#### **EOUIPMENT**

Include all equipment listed for normal vaginal delivery (see Chapter 177, Vaginal Delivery). Modern vacuum extractors are available from numerous suppliers. Both rigid and soft cups are available; each has advantages over the other. Rigid cups more often result in a successful assisted delivery, but they are also more likely to be associated with complications. The operator should be familiar with the models available at the institution and should be trained in their proper use. Any associated tubing or pumps must also be available. The Mityvac is one example of a vacuum apparatus (Fig. 169-2). Tucker-McLean (Fig. 169-3) and Simpson (Fig. 169-4) forceps are commonly used forceps with vertex presentation of term infants. Again, local availability and user training should determine the type of forceps employed. Both forceps and vacuum equipment should be readily available on all labor floors.

#### **PRECAUTIONS**

The Food and Drug Administration (FDA) published a public advisory in 1998 concerning complications resulting from vacuum deliveries. The FDA found a fivefold increase in death and serious injury after vacuum deliveries. Although part of this increase may be due to the increased use of this procedure, the blame may also lie in failing to follow established protocols. The most concerning complication is a life-threatening subgaleal hematoma. The length of application of the vacuum may also be an important factor in the development of complications. It is not recommended to apply a vacuum for more than 20 minutes.

Figure 169-2 Mityvac extractor.

Figure 169-3 Tucker-McLean forceps.

#### PREPROCEDURE PATIENT EDUCATION

Assisted delivery is a procedure that most women would choose to avoid during their labor. It is optimal to discuss the possibility of the need for vacuum or forceps delivery before a patient is in labor, but this is not always possible. Nonetheless, the risks and benefits of the procedure must be explained to the patient in as much detail as possible prior to attempting an assisted vaginal delivery. Consent for the procedure should be obtained.

## **TECHNIQUE**

# **Forceps Delivery**

The forceps have interlocking parts with a right and a left side that correspond to the side of the maternal pelvis in which they lie when applied. Each side has a handle, shank, and blade. The Simpson forceps is most commonly used for low and outlet deliveries.

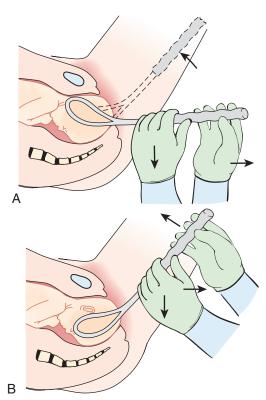

Initially developed by Dr. J. Bachman, the acronym ABCDEF-GHIJ has become part of the Advance Life Support in Obstetrics (ALSO) curriculum; it is useful when training for forceps- and vacuum-assisted deliveries. Except for F, G, and H, the acronym is essentially the same for both procedures:

- A: Is the *anesthesia* adequate? Consider a local or pudendal block or both. *Ask* for help.
- B: Is the bladder empty? Straight catheterize if needed.
- C: Is the cervix completely dilated?
- D: Determine the position of the fetal head. Consider shoulder dystocia (i.e., why is there a delay?).
  - Anterior fontanelle is larger and forms a cross.
  - Posterior fontanelle is smaller and forms a Y.
  - Find the ear, feeling which way it bends.
  - The descent should be to a +2 station, with the vertex filling the sacrum.

Figure 169-4 Simpson forceps.

- E: Is the *equipment* ready (e.g., infant suction bulb, cord clamp, instrument table)?
- F: Are the *forceps* ready for application?
  - 1. Articulate the forceps to ensure a proper fit.
  - Disarticulate the handles and take the left handle in your left hand (holding it like a pencil with concave cephalic curve toward the vulva and the shank directed upward, perpendicular to the floor).
  - 3. Begin to ease the forceps along the left side of the fetal head (OA); use your right hand to protect the maternal sidewalls and guide the blade into position. (The right thumb is placed on the heel of the blade and gently inserted.)
  - 4. Right forceps handle is then held in your right hand.
  - 5. Insertion is along the right side of the fetal head, with the left hand protecting the maternal right pelvis and guiding the blade into place.
  - If correctly applied, the handles should fit together easily and lock easily.
  - 7. Check the application position for safety (posterior fontanelle, fenestration, sagittal suture).
    - Posterior fontanelle should be midway between the shanks and 1 cm above the plane of the shanks.
    - Fenestrations of the forceps should admit no more than one fingertip.
    - Sagittal suture should be midline and midway between the shanks. (For OP deliveries, the blades should be equidistant from the midline of the face and brow.)
- G: Use gentle traction (i.e., Pajot's maneuver) (Fig. 169-5).
  - 1. The pelvic curve from the inlet through the outlet is described as a J-shaped curve.

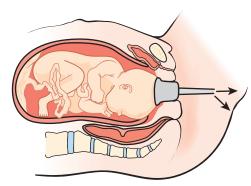

**Figure 169-5** Occiput anterior delivery by outlet forceps (Simpson). The direction of gentle traction for delivery of the head is indicated. Initially, the forceps are horizontal (**A**) and they are gradually rotated forward (**B**). Forces are as noted.

- 2. Initially, one hand pulls the forceps handles in the same direction that the handles extend (an approximately horizontal vector, outward and away from the mother).
- The other hand is placed on the shaft close to the perineum and pushes in a downward vector.
- The summation of these two vectors creates an outward-anddownward force.
- 5. As the crown of the head moves from under the symphysis, the traction should begin upward. (For OP deliveries, the horizontal traction continues until the base of the infant's nose passes under the symphysis.)
- H: The handle is elevated to follow the J-shaped pelvic curve (see Fig. 169-5B).
- I: Evaluate for the need for an episiotomy *incision*. The amount of distention of the perineum will dictate the need. (For OP deliveries, there will be greater distention of the vulva, and a large episiotomy may be needed.)
- J: The forceps are removed when the *jaw* of the infant is reachable.

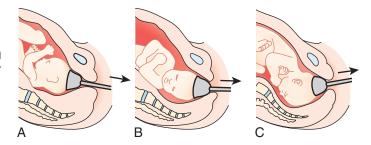

# **Vacuum Delivery**

- A: Is the anesthesia adequate? Ask for help.
- B: Is the bladder empty?
- C: Is the *cervix* completely dilated?
- D: Determine the position of the fetal head. Consider shoulder dystocia (i.e., why is there a delay?).
  - Anterior fontanelle is larger and forms a cross.
  - Posterior fontanelle is smaller and forms a Y.
  - Find the ear, feeling which way it bends.
  - Descent should be to a +2 station, with the vertex filling the sacrum.
- E: Equipment and extractor ready (infant suction bulb, cord clamp, instrument table, etc.)?
- F: Insert and apply the cup over the posterior fontanelle.
  - Wipe vertex clean of blood and fluid.
  - Spread the labia.
  - Compress and insert the cup.
  - Place the cup over the posterior fontanelle (or over the sagittal suture up to 3 cm in front of the posterior fontanelle, toward the face).
  - Sweep the finger around the cup to check for trapped maternal tissue.
  - Calibrate the vacuum dials, noting that yellow (10 mm Hg) is the resting suction and that red (50 mm Hg) is the suction pressure required for traction during contractions.
- G: Use gentle traction (Fig. 169-6).
  - 1. Apply traction at right angles to the plane of the applied surface of the cup.

**Figure 169-6** Correct position of the vacuum cup and the correct direction of traction before the vertex clears the symphysis pubis. (Modified from Epperly T, Breitinger R: Vacuum extraction. Am Fam Physician 38:205, 1988.)

**Figure 169-7** Occipitoposterior application (**A**), rotation (**B**), and delivery (**C**) using vacuum extractor. (Modified from Lowdermilk DL, Perry SE, Bobak IM: Maternity and Women's Health Care, 7th ed. St. Louis, Mosby, 2000.)

- Do not rock or torque the cup or handle. Only use gentle, steady traction.
- 3. As the fetal head moves around the symphysis and extends, the vacuum handle will rise from a horizontal to a nearly vertical position. (The angles and traction are more difficult for OP deliveries, with the handle often pointing toward the floor.)
- 4. If the cup detaches, consider the following problems: inadequate vacuum suction, trapped maternal tissue, a fetal scalp electrode in the way, incorrect application of the extractor (not over the flexion point), or bending or rotation of the shaft.
- H: Halt traction when the contraction is over.
  - 1. Reduce the vacuum to 10 mm Hg between contractions.
  - 2. Repeat the gentle-traction cycle with the next contraction.
  - 3. *Halt* the procedure if the cup disengages more than three times, if no progress is noted after three consecutive pulls, or if a delivery does not occur after 20 minutes of intermittent traction
  - 4. Use caution when attempting a forceps delivery after a failed vacuum extraction (only if the vertex is right on the perineum). A cesarean section may be a better choice (intracranial hemorrhage is more common after a failed vacuum extraction followed by a forceps delivery).
- I: Make an incision for episiotomy, if necessary. A midline episiotomy may be associated with increased risk of third- and fourth-degree perineal lacerations.
- J: Remove the vacuum cup when *jaw* of the infant can be reached or is delivered.

A suction application can also be used to rotate the head from an OP to an OA position before delivery (Fig. 169-7).

# **SAMPLE OPERATIVE REPORT**

The operative report from an assisted vaginal delivery should be included in the delivery note. The actual note will vary greatly depending on the individual labor and local custom. Following is an outline of suggested topics to include in this note:

- Preoperative diagnosis (note indication for the assistance, such as maternal exhaustion)
- Postoperative diagnosis (note preoperative diagnosis and result of the procedure [e.g., vaginal delivery, term infant, weight, Apgar score, cord pH])
- Operation (note outlet forceps or vacuum extraction)
- Instrument (e.g., Simpson forceps)
- First stage (note length, interventions, any complication)
- Second stage (same information as in first stage, including type of fetal monitoring)
- Third stage (type of placenta delivery, description of placenta)
- Repairs
- Bladder
- Estimated blood loss
- Anesthesia

#### **COMMON ERRORS**

- Starting the procedure too soon: Be sure that head is engaged and position is clear prior to attempting assisted vaginal delivery.
- Incorrectly positioning the instrument: Ensure proper placement of vacuum or forceps prior to pulling.
- Including vaginal tissue in the vacuum application: Circle finger around cup to ensure no tissue has been trapped between the cup and the head.
- Continuing with assisted vaginal delivery when success is unlikely: Be prepared to stop and proceed to a cesarean section if unable to deliver within 20 minutes or if vacuum "pops off" three times.

# **COMPLICATIONS**

- Cervical, vaginal, or perineal lacerations
- Postpartum hemorrhage from the lacerations
- Fetal birth trauma (e.g., fractured clavicle, cephalhematoma, lacerations, abrasions, facial nerve palsy, intracranial and retinal hemorrhage)
- Subgaleal hematoma
- Shoulder dystocia
- Neonatal scalp emphysema
- Cephalhematoma
- Hyperbilirubinemia
- Fetal cervical trauma
- Maternal discomfort at delivery
- Maternal urinary retention

#### POSTPROCEDURE PATIENT EDUCATION

Instrument-assisted deliveries increase the level of maternal concern for the infant. The provider should discuss the need for the instrument delivery and maternal perceptions regarding the delivery on the first postpartum day. After the procedure, the patient should be advised to monitor the following and report any changes to the practitioner:

- Bleeding
- Fever
- Dysuria and urinary retention
- Pelvic pain (could indicate hematoma)

# **CPT/BILLING CODES**

- 59400 Global vaginal delivery (antepartum, vaginal delivery with or without episiotomy and/or forceps or vacuum) and postpartum care
- 59409 Vaginal delivery *only* (with or without episiotomy and/or forceps or vacuum)
- 59410 Vaginal delivery *only* (with or without episiotomy and/or forceps or vacuum) including postpartum care
- 59610 VBAC (global)
- 59899 Unlisted procedure, maternity care and delivery (induction)

# **ICD-9-CM DIAGNOSTIC CODE**

669.51 Forceps or vacuum delivery, without mention of indication

# Intrathecal Analgesia in Labor

Thomas E. Howard • Renae Rasmussen

Intrathecal analgesia uses the subarachnoid (dural) space for the injection of analgesic narcotics and anesthetics. This space is filled with cerebrospinal fluid (CSF) and is the same space used for a spinal or saddle block (see Chapter 175, Saddle Block Anesthesia). Analgesics injected into this space diffuse through the CSF to coat the visceral pain receptors in the dorsal horn of the spinal cord (T10–L1). Although it does not provide complete pain relief, this technique provides considerably more pain relief than the parenteral or intravenous (IV) route. In addition, pain relief is more rapid than with epidural analgesia. In comparison to spinal or saddle block anesthesia, which often uses hyperbaric anesthetic solutions (i.e., solutions more dense than CSF so they drift caudally), the dose with intrathecal analgesia is significantly less. Overall, intrathecal analgesia allows for profound analgesia without clinically significant motor or autonomic blockade (i.e., minimal anesthesia).

This procedure is not technically difficult to perform and does not adversely affect the infant or the progress of labor. Clinicians comfortable with performing lumbar puncture can easily learn this procedure and perform it without an anesthesiologist. It is useful in many clinical settings, especially where epidural analgesia is not readily available or when complete anesthesia is not necessary (Box 170-1). It is also used in combination with epidural analgesia (combined spinal-epidural [CSE]).

Often performed with a needle-through-needle technique, CSE provides faster onset of analgesia with a smaller dose of anesthetic than epidural alone. Although it was thought, at one time, that a smaller dose of anesthetic would result in less motor block and maternal leg numbness and therefore improved mobility, it turns out this may not be the case. A recent Cochrane Review comparing CSE with epidural alone concluded that although there was no difference in postdural puncture headache (PDPH), progress of labor, incidence of instrumented deliveries or cesareans, or adverse effects on the infant, there was also no difference in maternal mobility during labor. Although analgesia was faster in onset with CSE, more women had pruritus than with epidural alone. Consequently, there was no difference in patient satisfaction in the CSE group compared with epidural alone.

Intrathecal analgesia is ideally suited for patients in the first stage of labor who are anticipated to deliver vaginally (if cesarean is anticipated, epidural or CSE may be preferred). The pain in this stage is primarily due to uterine contractions and cervical dilation. Pain in the second stage of labor is due to both uterine contractions and fetal descent through the birth canal. Because fetal descent stimulates the pudendal nerve (S2–S4), intrathecal analgesia is less effective; however, it does continue to provide analgesia for the uterine contractions. The real overall benefit for intrathecal analgesia is improved tolerance of the contractions, thereby resulting in a more rested mother for the second stage of labor. This in turn should enhance the overall birthing experience.

Because the duration of intrathecal analgesia is limited, it should be used as the sole method for pain control only when the remaining duration of the first stage of labor is expected to be less than 6 hours. Although the procedure can be repeated later in labor, each additional dural puncture increases the risk of PDPH. If a cesarean section becomes necessary, general, spinal, or epidural analgesia may be used after intrathecal analgesia.

#### **ANATOMY**

Intrathecal analgesia is produced when medications are injected directly into the thecal sac. Unlike an epidural injection, the intrathecal injection penetrates the dura and enters the space occupied by the CSF. The anatomy is identical to that for an adult lumbar puncture and this is described in detail in Chapter 206, Lumbar Puncture. The anatomy is also identical to that for saddle block anesthesia, as described in Chapter 175, Saddle Block Anesthesia.

#### **INDICATIONS**

- Active first stage of labor with anticipated vaginal delivery
- Epidural analgesia not available (many rural and community hospitals), not needed, or not desired

# **CONTRAINDICATIONS**

# **Absolute**

- Allergy to selected narcotics
- Patient refusal or uncooperative patient
- Patient with known coagulopathy
- Use of once-daily–dose low–molecular-weight heparin within 12 hours
- Refractory maternal hypotension

# Box 170-1. Advantages and Disadvantages of Intrathecal Narcotics in Labor

#### Advantages

Prolonged, superior analgesia compared with intravenous administration

No effect on expulsive forces in labor

Rapid onset of analgesia

Technique similar to lumbar puncture

Low incidence of serious side effects

Cost advantages compared with epidural anesthesia

# Disadvantages

Analgesia is usually inadequate for second stage of labor No anesthesia for instrumented delivery or episiotomy

Does not provide surgical anesthesia

Risk of respiratory depression

High incidence of mild side effects

May require a repeat injection, which increases the risk of postdural puncture headache

# **TABLE 170-1** Duration and Onset of Action for Intrathecal Narcotics

Medication	Dosage	Onset of Action (min)	Duration of Action (hr)	
Fentanyl	10–25 μg (usual dose 15 μg)	5	1.4–3.5	
Sufentanil*	2.5 μg	5–10	1–3	
Morphine <sup>†</sup>	0.1–1.0 mg <sup>‡</sup> (usual dose 0.15 mg)	15–60	2–6	

\*Although fetal outcomes were the same, bradycardia has been associated with higher doses of sufentanil; therefore, at Parkland Hospital, fentanyl or this dose of sufentanil are preferred.

<sup>†</sup>Astramorph and Duramorph are commercially available, preservative-free morphine preparations. It is important to use preservative-free medications to avoid the complication of arachnoiditis from the preservative.

\*Morphine at doses of 0.5–1.0 mg can have duration of action up to 12 hours but with a higher rate of side effects; it is therefore not recommended.

- Active infection at the site of puncture
- Increased intracranial pressure
- Supratentorial mass lesion
- Untreated maternal bacteremia

#### **Relative**

- Spinal abnormalities, such as marked scoliosis, making the procedure technically difficult
- Treated active systemic infection, such as that resulting in maternal bacteremia
- Cutaneous lesion/skin compromise of the lower back, such as cellulitis or dermatitis

# **EQUIPMENT AND SUPPLIES**

Spinal anesthesia kit, which includes sterile preparation materials, local anesthetic, a 25-gauge or smaller atraumatic spinal anesthesia needle, and an 18- or 19-gauge introducer

**NOTE:** Thin, atraumatic spinal needles (Sprotte or Whitacre needles, with rounded or pencil-point, conical ends) have been proven to decrease the risk of PDPH.

- Syringe with filter-tip needle for drawing up narcotic for injection
- Narcotic for injection (Table 170-1)
- Bupivacaine 0.5% to 0.75% suitable for spinal injection, 2.5 mg total
- Ephedrine for injection
- Naltrexone, 25-mg tablet
- Naloxone ampules, 0.4 mg
- Continuous fetal monitoring (internal or external)
- Sterile gloves
- Personnel to monitor for side effects, including monitoring blood pressure
- Pulse oximeter

# **PRECAUTIONS**

Intrathecal analgesia is a fairly safe procedure in the right clinical setting. Nonetheless, it should be approached with caution. The procedure should not be performed too early in labor unless another form of analgesia or repeat injection is planned. The injection should also not be performed too late in labor because the medication is primarily given to ease the discomfort of contractions; it is not as effective in the second stage of labor where much of the discomfort is due to descent of the fetus. Care should be taken to minimize the side effects, particularly the itching seen in many

patients. Finally, the provider should remember to avoid the possibility of introducing infection to the central nervous system by following aseptic technique and avoiding injection through an area that may be infected or compromised.

#### PREPROCEDURE PATIENT EDUCATION

The patient should be informed of available analgesia and anesthesia options during the prenatal period to aid in giving informed consent (see the sample patient consent form online at www. expertconsult.com). Preferably, desired analgesia or anesthesia should be determined as part of a written birthing plan. Staff providing prenatal education should be knowledgeable about this technique and offer information to their clients. An educational handout can be given to them to read before the onset of labor (see patient education form online at www.expertconsult.com). It should be explained to the mother that any analgesia/anesthesia during labor is optional and does have certain risks. It is not necessary to have any procedure for analgesia/anesthesia in order to have a healthy baby. However, excessive fatigue due to discomfort during labor is also unnecessary; it may affect not only the quality of labor but the ability to complete labor.

During labor, the clinician should review the benefits and risks with the patient and obtain informed consent. Ideally, because the pain of labor might impair the mother's understanding of this information, the counseling should be done in the presence of the mother's labor coach.

# **TECHNIQUE**

- 1. Ensure continuous fetal monitoring is in place and check for contraindications to intrathecal analgesia.
- 2. Obtain informed consent.
- Establish IV access and, if possible, give a 500-mL bolus of fluid to help prevent the rare side effect of maternal hypotension (give this bolus very slowly for women with pregnancy-induced hypertension).
- 4. Place the patient in the desired position for dural puncture (sitting or lying on left side) and locate the L3-4 interspace (Fig. 170-1).

**Figure 170-1** To locate the L3-4 interspace, the iliac crests are palpated. The line between the crests intersects the L4 spinous process. The L3-4 interspace is found slightly above (cephalic to) the L4 spinous process.

- 5. Perform sterile preparation and draping. Administer the local skin anesthetic as you would for a lumbar puncture.
- 6. Insert the introducer needle through the anesthetized skin and into the supraspinous ligament. It is especially important to use an introducer in larger patients because the spinal needle is otherwise difficult to direct. Spinal anesthetic needles used for this procedure are thinner and less rigid than the needles most clinicians use for lumbar puncture. The advantage of the narrower-gauge, atraumatic needles is that they lower the risk of PDPH.
- 7. Draw up selected rapid-onset narcotic (fentanyl or sufentanil) in a syringe with a filter-tip needle (filter prevents drawing up tiny glass particles).
- 8. If desired, also draw up preservative-free morphine into the same syringe with the filter-tip needle. The decision to add morphine in part depends on the anticipated length of time needed for analgesia; adding morphine prolongs the duration (see Table 170-1). Use of morphine has also been shown to decrease the need for postpartum pain medications and to enhance the pain relief with subsequent epidural analgesia.
- 9. In the same syringe, draw up 2.5 mg of bupivacaine. Ensure that the bupivacaine is suitable for spinal anesthesia. Bupivacaine at much higher doses is commonly used to obtain complete surgical anesthesia. This small dose of bupivacaine increases the duration while decreasing the time to onset of analgesia compared with using a narcotic alone. Its use also reduces the incidence of pruritus.
- 10. Insert a narrow-gauge, bullet-type or pencil-point atraumatic anesthetic needle (25 to 27 gauge) through the introducer into the intrathecal space. You will detect a distinct pop or snap when passing through the ligamentum flavum (this pop may be less pronounced with atraumatic needles). Whereas minimal or no fluid returns when passing through the epidural space, CSF returns when the intrathecal space has been entered (just as with a lumbar puncture). Remove the trocar from the anesthesia needle and confirm that CSF is flowing into the hub of the needle.
- 11. Place the syringe with the narcotic and anesthetic agents onto the spinal needle. Aspirate a small amount of CSF (0.25 to 0.5 mL) into the syringe, allowing it to mix with the medications in the syringe, and then inject the contents of the syringe back through the needle over 5 to 10 seconds. Aspiration and injection should be performed between contractions.
- 12. Remove the spinal needle, introducer, and syringe as a unit and place the patient on her left side for uterine displacement. Monitor her pulse and blood pressure every 5 minutes for 15 minutes; if stable, she can then move to a more comfortable position. Maternal hypotension (rare) occurs soon after the medication is given, if it is going to happen. If this occurs, it should be treated with another IV fluid bolus and with ephedrine 5 to 10 mg IV push. This ephedrine dose can be repeated every 5 minutes as necessary.

- 13. If pain relief diminishes before delivery, there are four options:
  - Intrathecal narcotic and bupivacaine can be repeated, especially if the patient is still in the first stage of labor.
  - A supplemental parenteral narcotic injection can be given.
     However, it is important to give this at half the usual dose to avoid the side effect of respiratory depression.
  - Epidural analgesia can be administered.
  - Some anesthesiologists perform CSE. To do this, an epidural catheter is placed at the time of the intrathecal injection and can be used later if operative delivery is necessary, or if added pain relief is desired.

## SAMPLE OPERATIVE REPORT

See a sample operative report online at www.expertconsult.com.

#### **COMMON ERRORS**

- Incorrect dosing of medications: Be certain that medications are properly labeled and dosed. The use of multiple medications with different dosing scales can lead to confusion and medication errors.
- Failure to monitor patient: The peak of respiratory depression that may develop after injection usually occurs after delivery of the infant. Patients who receive intrathecal injections should be monitored in the postpartum area for signs of respiratory depression for at least 12 hours after the injection.
- Insufficient pain relief: Intrathecal injection works well in most instances, but may not be effective for all patients. Dosing may need to be repeated or alternative forms of analgesia used. If multiple doses or multiple routes of analgesic administration are used, be certain to monitor closely for deleterious effects of the medications.

# **COMPLICATIONS**

Although serious complications with intrathecal analgesia are rare, the incidence of less severe side effects is relatively high (Table 170-2). Pruritus, although seldom severe, is quite common. However, only about one third of patients request treatment for pruritus. It responds to naloxone at the doses listed. However, the analgesic effect may be affected by naloxone. Nalbuphine (Nubain) is an opioid agonist—antagonist that can be used for pruritus alone. Another option is diphenhydramine (Benadryl). Nausea and vomiting are treated symptomatically. For PDPH, oral or IV caffeine or use of an autologous blood patch may be helpful. See Chapter 206, Lumbar Puncture, for these treatments.

There are no adverse fetal outcomes expected from this procedure. Rarely (<10% of cases), fetal heart rate decelerations are seen and these are generally transient. Fetal heart rate monitoring is recommended according to institutional protocols. There is no effect on the normal course of labor at the suggested doses of agents.

TABLE 170-2 Side Effect	TABLE 170-2 Side Effects and Their Management for Intrathecal Analgesia in Labor				
Side Effects	Incidence	Treatment			
Pruritus (usually mild)	≥50%	May not be related to histamine release, but can try diphenhydramine (Benadryl) 20–50 mg orally, IM, or IV every 6 hr as necessary or naloxone (Narcan) 0.2–0.4 mg IV.			
Nausea and vomiting	30%-50%	Metoclopramide (Reglan) 10 mg orally or IV every 6 hr or promethazine (Phenergan) 25 mg IM every 6 hr.			
Urinary retention	4%-20%	In-and-out catheterization as necessary.			
Postdural puncture headaches	1%–6%	Usually no treatment is necessary. Blood patch if not resolved with conservative management (rest, fluids, analgesics, caffeine).			
Maternal hypotension	Up to 15%	Generally transient. If systolic blood pressure <90 mm Hg or any fetal distress, use IV fluid bolus, uterine displacement, and/or ephedrine (5–10 mg IV push). Repeat every 5 min as necessary.			
Respiratory depression	0.2%-0.4%	Naloxone (Narcan) 0.2–0.4 mg IV. Consider oxygen with decreased SaO <sub>2</sub> .			

<b>TABLE 170-3</b>	Sedation Scale to Monitor for
Respiratory	Depression from Intrathecal Narcotics

Sedation Level	Assessment
None Minimal Moderate	Awake and alert Drowsy or sleeping but easily aroused Drowsy or sleeping but not easily arousable
Somnolent	Drowsy or sleeping and cannot be fully aroused

#### POSTPROCEDURE MANAGEMENT

Vital signs (respiratory rate, heart rate, and blood pressure) are monitored every 30 minutes for the duration of labor. Increased monitoring should be maintained after delivery until the analysesic is metabolized. Nursing staff should assess for sedation and arousability (Table 170-3).

If moderate or somnolent sedation is noted by nursing staff, the clinician should be notified and the patient's oxygen saturation (SaO<sub>2</sub>) checked. Use naloxone for treatment of respiratory depression at doses of 0.2 to 0.4 mg IV. This can be repeated every 3 minutes until the respiratory depression or sedation is reversed. Administer oxygen if the SaO<sub>2</sub> is diminished. Naloxone can also be given by a continuous IV infusion at 0.4 mg/hr if necessary. Although the exact mechanism is unknown, respiratory depression may be caused by ascending spread of the analgesic agent. In theory, if the narcotic spreads too far cephalad, it can suppress the respiratory centers in the fourth ventricle of the brain. The incidence of respiratory depression peaks at between 4 and 9 hours, but it has been noted as late as 12 hours after administration of intrathecal narcotics. The time of highest risk for the mother is after delivery, when her respiratory drive may be decreased. Unfortunately, this is also a time when mothers are monitored less frequently. Some protocols call for postpartum continuous pulse oximetry or frequent hands-on measurement of vital signs and mental status.

Oral naltrexone 12.5 to 25 mg is given within 30 minutes after the delivery. This is a long-acting narcotic antagonist that reduces the side effects of the intrathecal narcotic, including the risk of respiratory depression, and is generally free of side effects at these dosages.

# **PATIENT EDUCATION GUIDES**

See examples of patient education and consent forms online at www.expertconsult.com.

## **CPT/ BILLING CODES**

62273 Injection, lumbar epidural, of blood or clot patch

62311 Injection, single (not via indwelling catheter), not including neurolytic substances, with or without contrast, of diagnostic or therapeutic substance(s) (including anesthetic, antispasmodic, opioid, steroid, other solution), epidural or subarachnoid; lumbar, sacral (caudal)

# **ICD-9-CM DIAGNOSTIC CODES**

V22.2 Pregnant state, NOS

650 Normal delivery

The fifth digit (X) is required for codes 640–648, 651–659, and 660–669 to denote the current episode of care:

- 0 Unspecified
- 1 Delivered, with or without mention of antepartum condition
- 2 Delivered, with mention of postpartum complication
- 3 Antepartum condition or complication
- 4 Postpartum condition or complication

- 644.23 Premature labor with delivery (<37 weeks)
- 646.83 Other specified condition of labor (pain)
- 652.23 Breech presentation
- 653.53 Unusually large fetus causing disproportion

# Codes Related to Deliveries with Forceps or Vacuum

- 662.03 Prolonged first stage of labor
- 662.23 Prolonged second stage of labor
- 659.73 Abnormality in fetal heart rate or rhythm or fetal distress

# Intrauterine Pressure Catheter Insertion

Beth A. Choby

The intrauterine pressure catheter (IUPC) allows for direct intrauterine monitoring of contraction strength and frequency when external tocodynamometry is ineffective. Approximately 20% of laboring patients in the United States are monitored using an IUPC. IUPC placement is appropriate for specific intrapartum indications. Maternal indications include excessive movement or elevated body mass index. IUPC use is common with protracted/dysfunctional labor and increasingly used during trial of labor after cesarean (TOLAC). When meconium or significant variable decelerations are present, IUPC placement allows for amnioinfusion.

Intrauterine pressure monitoring was first developed in the 1860s using intrauterine balloons placed transabdominally to determine contraction strength. The current transcervical route for IUPC placement was developed in the late 1960s, when one clinical monitoring unit became available that concurrently monitored fetal heart rate and contractions. Early IUPC technology determined intrauterine pressure using a column of water, although this was later replaced by an electronic microtip pressure sensor.

Today's IUPC technology uses either electronic pressure transducer-tip catheters or air-coupled flexible balloon catheters. Both types graphically represent intrauterine pressure through measurements of the frequency, duration, and amplitude of contractions. In women with arrest of labor, internal monitoring allows for an assessment of contraction strength with Montevideo units (MvU). Montevideo units are calculated as the product of contraction intensity multiplied by frequency (i.e., number of contractions in a 10-minute period multiplied by the mean amplitude of contractions during this time). During active labor, individual contraction amplitude ranges from 30 to 80 mm Hg; calculated Montevideo units between 180 and 220 are considered adequate. Demonstrating a pattern of 200 MvU for at least 2 hours during active labor is a reasonable criterion for making the diagnosis of failure to progress (Miles and colleagues, 2001).

Whether women with a previously scarred uterus attempting TOLAC benefit from IUPC monitoring is uncertain. An elevated uterine resting tone or abnormalities in the contraction pattern may suggest uterine rupture, although the best predictor seems to be an abnormal fetal heart tracing (variable or late decelerations). Fetal indications for an IUPC include amniotic fluid sampling and meconium dilution through amnioinfusion (discussed in Chapter 176, Transcervical Amnioinfusion).

# **INDICATIONS**

Eighty-five percent of patients in labor in the United States are managed using continuous fetal monitoring. Surveillance with external monitoring for fetal heart rate and contractions is most frequently used. When external monitoring is not possible, internal monitoring with a fetal scalp electrode and IUPC is sometimes necessary. Indications for an IUPC include the following:

- Inadequate contraction pattern
- Failure to progress/descend
- Arrest of labor
- TOLAC
- Ineffective use of external monitoring secondary to maternal motion or body habitus
- Need for amnioinfusion
  - Amniotic fluid sampling
  - Meconium dilution
  - Oligohydramnios with variable decelerations

#### **CONTRAINDICATIONS**

### **Absolute**

- Intact fetal membranes (absolute unless rupture acceptable; see Chapter 164, Amniotomy)
- Complete placenta previa

#### Relative

- Inadequately dilated cervix
- Partial placenta previa
- Vasa previa
- Uterine bleeding of undetermined etiology
- Nonreassuring fetal status
- Fetal anomalies (e.g., gastroschisis)

## **EQUIPMENT AND SUPPLIES**

- Sterile gloves
- Amniotomy hook if membranes are not ruptured
- Intrauterine pressure catheter (sterile; Fig. 171-1)
- Cable to join IUPC with fetal monitor (nonsterile)
- Fetal monitor
- Intravenous tubing, pole, and fluid if amnioinfusion is planned (see Chapter 176, Transcervical Amnioinfusion)

# **PRECAUTIONS**

- Ascertain fetal presentation to avoid traumatizing fetus.
- Ascertain placental location to avoid traumatizing the placenta.

# PREPROCEDURE PATIENT EDUCATION AND FORMS

The patient's medical record and progress in labor are reviewed. If the placental location is unknown, bedside ultrasonography confirms whether a partial or complete placenta previa is present.

**Figure 171-1** Intrauterine pressure catheter. (Courtesy of Utah Medical Products, Inc., Midvale, Utah.)

Indications for IUPC placement and risks and benefits of the procedure are discussed with the patient in a manner consistent with providing informed consent.

The patient is placed in dorsal lithotomy position. A cervical examination is necessary to determine cervical dilation and fetal presentation. If the membranes are unruptured, artificial rupture may be performed during the cervical examination if appropriate. IUPC placement is not usually painful, although some women experience mild discomfort during the procedure.

## **TECHNIQUE**

- Read the package insert to ensure familiarity with the equipment.
- 2. Ensure that all necessary supplies are present. Prepare a sterile field on the delivery bed or table.
- Turn on the fetal monitor. Connect the interface cable (nonsterile) to the fetal monitor. Switch the fetal monitor from the external tocometer setting to the IUPC setting.
- 4. Open the IUPC package. Don sterile gloves. Remove the IUPC and plastic introducer (guide) from the package and observe the double hatch marks at 45 cm. Hand the end of the IUPC that connects to the interface cable to an assistant.
- Establish a "0" baseline for the monitor as described by the manufacturer.
- 6. Perform a sterile vaginal examination to assess cervical dilation and confirm that the membranes are ruptured. Place the index and third fingers posteriorly between the fetal vertex and cervix. Position the fingers away from the area above which the placenta is located.
- 7. Use the opposite hand to slide the IUPC/plastic introducer into the vagina over the palmar aspect of the intravaginal hand. Pass the catheter through the vagina and into the cervical os. Stop advancement of the IUPC/introducer when the tip of the IUPC rests between the fingers of the examining hand.
- 8. Hold the plastic introducer with the intracervical fingers and push the external (outside) part of the IUPC with the opposite hand to advance it through the introducer. The IUPC should pass the fetal vertex with minimal resistance and advance into the amniotic sac.
- Stop advancing the IUPC when the double hatch marks (45 cm) reach the maternal introitus or when resistance is felt. IUPC advancement should proceed smoothly and without resistance. If resistance is encountered, change the direction of the

- catheter until insertion proceeds easily. Do not force the catheter because this increases the risk for placental, uterine, or fetal damage. Planning for insertion in an area remote from the placenta decreases risk for iatrogenic abruption. The double hatch marks correlate with normal placement of the IUPC. Checking for a flash of amniotic fluid in the IUPC channel during insertion is recommended to guard against extramembranous placement.
- 10. With the IUPC properly positioned, hold the external IUPC with the external hand. Remove the intravaginal hand and use it to "peel" the introducer away from the IUPC as the introducer is simultaneously pulled out of the vagina. Take care not to remove the IUPC when the introducer is being removed.
- 11. Connect the distal end of the IUPC to the interface cable. Secure the IUPC to the patient's thigh using the belt or adhesive pad provided. Leave some slack between the introitus and the belt to prevent inadvertent IUPC expulsion with patient repositioning or movement. Proper IUPC placement is again confirmed by checking that the double hatch marks are at the introitus.
- Confirm that connections between the IUPC and the reusable monitor cable and from the monitor cable to the monitor are all secure.
- Have the patient cough or perform a Valsalva maneuver to check for proper IUPC functioning. Palpable contractions should correlate with increased intrauterine pressure on the monitor.
- Write a brief procedural note in the chart. When amnioinfusion is indicated, please refer to Chapter 176, Transcervical Amnioinfusion.

#### INTRAUTERINE PRESSURE CATHETER REMOVAL

Removal of the IUPC is straightforward and usually performed before delivery. Apply traction to the IUPC between contractions. The IUPC should come out easily. If resistance is encountered, stop and redirect the catheter until it can be removed with minimal resistance.

# SAMPLE OPERATIVE REPORT

See a sample operative report online at www.expertconsult.com.

#### **COMMON ERRORS**

- Extramembranous placement. This problem occurs when the IUPC is positioned between the uterine wall and the amniotic/ chorionic membranes. Complications include placental perforation, uterine perforation, and abruptio placentae. Estimates of the frequency of incorrect IUPC placement range from 14% to 38% (Lind, 1999). The percentage of intra-amniotic placements increases if the clinician watches for a flash of amniotic fluid each time an IUPC is being inserted.
- Inability to thread the IUPC into the amniotic cavity. Redirect the IUPC tip and gently reintroduce. As the fetal head descends, placement becomes more challenging.
- The baseline tone on the uterine monitor is above zero. Re-zero the IUPC using the slide switch on the base of the IUPC.
- No contraction pattern is evident after the IUPC is zeroed. Suspect extramembranous placement. Withdraw the IUPC and check for blood in the IUPC tip.

#### **COMPLICATIONS**

- Extramembranous (extraovular) placement of the IUPC
- Inaccurate pressure tracings
- Placental perforation

- Uterine perforation
- Fetal vessel laceration
- Fetal trauma
- Amnionitis
- Disseminated intravascular coagulation (rare)
- Maternal cardiac failure secondary to amniotic fluid embolus (rare)

# POSTPROCEDURE MANAGEMENT AND PATIENT EDUCATION

The fetal heart rate and contraction pattern are monitored closely to ensure fetal and maternal well-being. Vaginal bleeding should be reported. Counsel the patient that mobility is limited with an IUPC. The patient can be disconnected from the monitor but should ask for assistance when she needs to get out of bed. Some providers prefer placing Foley catheters in women who have internal monitors.

# **CPT/BILLING CODES**

Although there is no CPT code for IUPC insertion, labor that is post-term, augmented/induced, or complicated can be billed in addition to a routine delivery charge. Code this increased acuity of care using hospital evaluation and management (E/M) codes. Obstetric care and delivery charges should be submitted in addition to these codes.

99356 Prolonged physician service in the inpatient setting, requiring direct (face-to-face) patient contact beyond the usual service first hour\*

99357 Each additional 30 minutes\*

99358 Prolonged evaluation and management service before and/ or after direct (face-to-face) patient care (e.g., review of extensive records and tests, communication with other professionals and/or patient/family); not face-to-face care; first hour\*

99359 Each additional 30 minutes\*

# **ICD-9-CM DIAGNOSTIC CODES**

658.0X Oligohydramnios

658.4X Infection of amniotic cavity

661.0X Abnormality of forces of labor

662.1X Prolonged labor

665.1X Rupture of uterus during labor

792.3 Nonspecific abnormal findings in fluid surrounding fetus

"X" indicates the need for a fifth digit for complete coding: 0, unspecified as to episode of care; 1, delivered; 3, antepartum condition.

# **OBSTETRIC ULTRASONOGRAPHY**

Thomas A. Kintanar

Ultrasound is defined as the range of sound waves with frequencies greater than 20,000 cycles per second (Hz), and they are undetectable by the human ear. Most ultrasound scanners use frequencies of from 1 to 10 MHz; 3 to 5 MHz are the most common for obstetric transabdominal examinations, although 2 to 2.25 MHz may be needed for obese patients. According to natality data, ultrasonography is being used more commonly in the United States. In 2002, 67% of mothers who had live births underwent ultrasonographic scanning during pregnancy, compared with 48% in 1989.

To evaluate the use of ultrasonography as a routine screening procedure during pregnancy, the National Institutes of Health (NIH) sponsored a landmark Consensus Development Conference in 1984. The consensus was that routine screening was not justified and that ultrasonography should be used only for specific indications. Those indications have remained fairly constant and are similar to those listed in the Indications section. This consensus was further supported by evidence from the large RADIUS study (N = 15,151), published in 1993 (Ewigman and colleagues), although there continues to be controversy regarding this study, specifically over whether the study population is generalizable (e.g., 93% of women in the study were white, 71% had at least some college education). The current position of the American College of Obstetrics and Gynecology (ACOG) allows the clinician and patient to opt for screening, but does not recommend routine use. As it turns out, the majority of women will develop one of the indications listed by the Consensus Development Conference during pregnancy.

The U.S. consensus regarding screening is not a worldwide consensus. The Royal College of Obstetricians and Gynecologists and the European Committee for Ultrasound Radiation Safety endorse routine prenatal ultrasonographic examinations. Ultrasonography is routinely used in several European countries, including Sweden and Germany. The Canadian Task Force on Preventive Health Care finds fair evidence for routine ultrasonographic screening in the second trimester, even in women without clinical indications. Many U.S. insurers, including managed care organizations, now reimburse for routine obstetric ultrasonographic screening. The advent of three- (3D) and four-dimensional (4D) ultrasonography (3D imaging is three-dimensional in appearance; 4D is 3D imaging in real time) has conferred some proprietary advantages in terms of the quality of fetal features appreciated (recent literature cites improved diagnosis of facial anomalies, skeletal malformations, and neural tube defects with 3D and 4D ultrasonography).

**EDITOR'S NOTE:** Routine first-trimester scanning in a high-risk population to confirm gestational age is very helpful (investigators have proven it more accurate than last menstrual period), especially when later managing intrauterine growth retardation (IUGR) or postdate pregnancies (in two studies, postdate deliveries and inductions were reduced by more than 50%). Such accurate dating may also alter the method of pregnancy termination; conversely, its use may improve maternal bonding.

Obstetric ultrasonography can be performed transabdominally, transvaginally, or transperineally (or a combination), with transabdominal and transvaginal scanning being used much more frequently than transperineal. Transvaginal scanning is performed predominantly in the first trimester and usually facilitates visualization of fetal structures 1 week earlier than with transabdominal scanning. Transvaginal and transperineal scanning may also be useful during the second and third trimesters for scanning the cervix and endocervical areas in cases of preterm labor, incompetent cervix, and placenta previa.

Ultrasonography can detect 35% to 50% of major fetal malformations, but its sensitivity is very technician or clinician dependent. It is important for the clinician performing the examination to have adequate training and equipment and a willingness to seek appropriate consultation for complicated cases. Although a complete survey of fetal anatomy can often be performed by the end of the first trimester, the American Institute of Ultrasound in Medicine (AIUM) suggests that such a survey is best if performed after 18 weeks.

Obstetric ultrasonographic studies are classified in three different ways: for billing purposes, radiologically, and by training requirements. For billing purposes, a standard (survey), a limited (e.g., in emergencies, to evaluate a single organ, to guide a procedure, to answer a clinical question [e.g., "Is there fetal heart activity," or "Is there a placenta previa?"]), or a follow-up (to a standard scan) scan has been performed. Radiologically, a standard (also termed basic), a limited, or a specialized (targeted) scan is performed (the terms level I and level II scans are outdated). A limited scan is a goal-directed search for a problem or finding, and in most cases is appropriate only when a prior standard scan is already in the medical record (exceptions include women with no prenatal care). A specialized evaluation is done to identify, characterize, or exclude fetal anomalies, often based on an abnormal history, maternal serum screening results, or an abnormal standard scan, and is usually performed by individuals with special expertise. The American Academy of Family Physicians, the Advanced Life Support in Obstetrics (ALSO) advisory board, and others classify ultrasonographic applications as either basic or extended. With basic applications (e.g., most of the intrapartum indications), practicing clinicians with a base of knowledge in maternal-fetal anatomy and physiology can usually master scanning in a 1-day workshop. For extended applications, significant additional study and supervised practice are needed such as can be obtained in residency or other training programs. More advanced applications, such as measurement of Doppler velocimetry, require specialized training and are beyond the scope of this chapter.

# **DOCUMENTATION**

Adequate documentation for every ultrasonographic study is essential. This should include a permanent written report, complete with the ultrasonographic images incorporating measurement parameters and anatomic findings. Figure 172-1 is an example of an ultrasonography report form. Suggested documentation (adapted from the

AIUM guidelines) for first-trimester, second- and third-trimester, and intrapartum scans is discussed in the following sections. Only standard obstetric ultrasonographic studies are discussed here, and they should include the elements described in the following sections.

# First-Trimester Standard Scan Documentation

- 1. Document the location of the gestational sac. If visible, the embryo should be identified and the crown–rump length (CRL) measured and recorded. If an embryo is not visible, the mean gestational sac diameter should be recorded and can be used for estimating gestational age (Box 172-1).
- Report the presence or absence of fetal life (e.g., cardiac or somatic activity). With transvaginal scanning, cardiac activity is usually observed when the embryo is 5 mm or greater in length; if not, a later scan may be needed to document cardiac activity.
- 3. Document fetal number.

# Box 172-1. Indicated Dating Parameters Based on Gestational Age

- 1. From 7-10 wk: use an average of GS and CRL
- 2. From 11–14 wk: use an average of CRL, BPD, and FL, although CRL most accurate
- 3. From 15–28 wk: use an average of BPD, HC, FL, and AC; BPD most accurate, AC least accurate
- After 28 wk: use an average of BPD (with CI), HC, FL, and AC; discard any that are significantly different from others

AC, abdominal circumference; BPD, biparietal diameter; CI, cephalic index; CRL, crown–rump length; FL, femur length; GS, gestational sac; HC, head circumference.

- Assess embryonic/fetal anatomy to ascertain that it is appropriate for the first trimester.
- Perform an evaluation of the uterus (including the cervix), adnexal structures, and the cul de sac for any abnormalities.
- 6. Fetal nuchal translucency should be measured between 11 and 14 weeks.

# Second- and Third-Trimester Standard Scan Documentation

- 1. Document fetal life, number, presentation, and activity.
- 2. Report a quantitative and qualitative estimate of the amount of amniotic fluid (increased, decreased, normal; amniotic fluid index [AFI], single deepest vertical pocket, 2-diameter pocket).
- Record the placental location and determine its relationship to the internal cervical os. The umbilical cord should be imaged and the number of vessels evaluated, when possible.
- 4. Assess gestational age using a combination of biparietal diameter (BPD; or head circumference) and femur length. Abdominal circumference can also be used to assess gestational age (see Box 172-1).
- 5. Assess fetal growth with the abdominal circumference measurements. If previous studies have been performed, give an estimate of the appropriateness of the interval growth. Fetal weight should be estimated in late second- and all third-trimester scans. It can be estimated from BPD, head circumference, abdominal circumference, and femoral diaphysis length. Significant discrepancies between gestational age and fetal weight may suggest the possibility of fetal growth abnormality, intrauterine growth restriction, or macrosomia.
- 6. Perform an evaluation of the uterus, cervix, and adnexal structures.
- 7. The study should include, but not necessarily be limited to, the following fetal anatomy: head and neck, lateral cerebral ventricles, midline falx, cavum septum pellucidum, choroid plexus, cisterna magna, cerebellum, four-chamber view of heart, spine (cervical, thoracic, lumbar, and sacral), stomach (presence, size, and site), diaphragm, kidneys, urinary bladder, umbilical cord insertion site, number of umbilical vessels, extremities (presence and number), intactness of the anterior abdominal wall, and sex (medically indicated only in low-risk pregnancy with multiple gestations to possibly determine number of chorions).

# **Intrapartum Standard Scan Documentation**

- 1. Document fetal life, number, and presentation.
- 2. Report an estimate of the amount of amniotic fluid.
- 3. Record the placental location and determine its relationship to the internal cervical os.

# **INDICATIONS**

- Confirmation of pregnancy
- Vaginal bleeding of undetermined etiology during pregnancy
- Determination of fetal presentation/presenting part
- Suspected multiple gestations
- Estimation of gestational age
- Evaluation of fetal growth, including multiple gestations
- Significant uterine size/dates discrepancy
- Pelvic mass/pain
- Suspected hydatidiform mole
- Suspected ectopic pregnancy
- Suspected fetal death (see Chapter 225, Emergency Department, Hospitalist, and Office Ultrasonography [Clinical Ultrasonography])
- Suspected uterine abnormality
- Intrauterine contraceptive device localization (see Chapter 225, Emergency Department, Hospitalist, and Office Ultrasonography [Clinical Ultrasonography])

- Ovarian follicle development surveillance for infertility
- Biophysical profile (BPP) or modified BPP (nonstress test combined with AFI)
- Suspected polyhydramnios or oligohydramnios
- Follow-up evaluation of placental location for identified placenta previa
- Suspected placental abruption
- Premature rupture of membranes or preterm labor (e.g., estimation of fetal weight and/or presentation and/or cervical dilation)
- Evaluate need for cervical cerclage placement
- Evaluation of fetal condition in late registrants for prenatal care
- Observation of intrapartum events
  - Management of second twin
- Manual removal of placenta
- Adjunct to special procedure
  - Amniocentesis
  - External cephalic version
  - In vitro fertilization/embryo transfer
  - Chorionic villous sampling
- Measure nuchal translucency as part of a screening program for fetal aneuploidy
- Follow-up observation of identified anomaly\*
- History of previous infant with congenital anomaly\*
- Abnormal maternal serum markers for an euploidy or neural tube defects (screening for anomalies)\*
- Evaluation of fetal well-being by Doppler flow velocities in suspected IUGR\*

#### **CONTRAINDICATION**

Maternal refusal is the only contraindication.

# **EOUIPMENT**

- Real-time ultrasonography machine with either a 3-MHz or higher transducer for transabdominal or transperineal scans (2 to 2.25 MHz may be needed for obese patients) or a 5-MHz or higher transducer for transvaginal scans (Among state-of-the-art machines, differences between manufacturers are primarily subjective [see the Suppliers section].)
- Ultrasonic gel
- Towels to remove gel when study completed
- Sheaths, probe covers, or a glove for transvaginal or transperineal scanning
- Appropriate forms for documentation

# PREPROCEDURE PATIENT PREPARATION

If the pregnancy is more than 20 weeks along, the bladder should be empty if performing transabdominal scanning. The patient's bladder should be empty or only slightly full for transvaginal or transperineal scanning. Patients should know about the necessary position (recumbent or semirecumbent for transabdominal or transperineal; dorsal lithotomy for transvaginal or optionally for transperineal scanning), and to expect the insertion of a probe for transvaginal scanning.

Issues to be discussed with patients who undergo obstetric ultrasonography include the following:

- Safety
- Purpose of the examination
- Detection of birth defects
- · Accuracy of measurements
  - Dating
  - Estimated fetal weight

<sup>\*</sup>Usually a targeted examination performed by individuals experienced in this area.

After many years, no study of safety has ever indicated more than a theoretical risk to the fetus from routine ultrasonographic scanning (see the Complications section). AIUM is a not-for-profit national professional organization that continues to monitor ultrasonography safety. They have never noted any safety problems (for mother or child) with ultrasonography. However, the clinician should comment that ultrasonographic examinations are generally performed in the United States only for indications and that the least amount of ultrasound that is necessary will be used to obtain the needed information.

When asked why they think an ultrasonographic examination is being performed, patients commonly state "to make sure the baby is okay." It may be important to explain that the examination is being performed to answer a particular clinical question, not for general screening. They should be aware, especially if a limited study is being performed, that no ultrasonographic study can ensure a perfect infant. Patients also frequently request ultrasonography to determine the sex of the infant. They should be informed that national guidelines (NIH or otherwise) do not list this as an indication for ultrasonography. After providing this information, it is the clinician's choice as to whether to attempt to determine the sex of the infant

A handout for the patient to review before scanning can be quite helpful (see the sample patient education form available online at www.expertconsult.com). After scanning, giving the patient a picture of the fetal hand profile, the facial profile, or even the genitalia should enhance bonding with minimal legal hazard.

### **TECHNIQUE**

- 1. For transabdominal scanning, the mother is usually most comfortable in the recumbent or semirecumbent position, tilted slightly to her left or with slight left lateral hip displacement. An adequate amount of gel should be applied to the abdomen. This position can also be used for transperineal scanning if the legs are flexed and wide apart. For transvaginal (and often for transperineal scanning), the mother is placed in the dorsal lithotomy position. An adequate amount of gel should be applied to the tip of the transducer before it is inserted into the sheath or glove for transvaginal or transperineal scanning.
- 2. By convention, transabdominal scanning is performed with the clinician on the right side of the bed, and the transducer position and image orientation are described relative to the mother (not the body of the fetus). When the marker dot of the transducer is located toward the mother's head, a longitudinal (sagittal) scan is performed; the mother's head will be located beyond the left side of the image (cranial direction) and her feet beyond the right side (caudal direction). When the marker dot is placed on the mother's right side, a transverse image is produced; the mother's right side will be located on the left side of the image and vice versa. (See Chapter 225, Emergency Department, Hospitalist, and Office Ultrasonography [Clinical Ultrasonography], for a more complete discussion of orientation.) By convention, transvaginal and transperineal scanning follow the same orientation for images.
- 3. For transvaginal scanning, additional gel is applied to the outside of the sheath and the transvaginal transducer is introduced into the vagina. Scanning starts as soon as the transducer is inserted; avoid inserting the transducer too far, which can cause the clinician to miss the cervix and lower uterine segment. The transducer handle is moved to the opposite side of the vaginal opening to evaluate the adnexa (e.g., the transducer handle is moved to the mother's right side to evaluate her left adnexum).
- 4. For transperineal scanning, use the same transducer as for abdominal scanning. Additional gel is applied to the outside of the sheath or glove covering the transducer and the transducer is then placed against the introitus, labia, and perineum. During

- transperineal scanning, the vagina appears as a bright line usually meeting the cervix at a 90-degree angle. The distance from the perineum to the cervix usually places the cervix at an ideal distance for (and within) the focal zone of the transducer. Bowel gas in the rectum can sometimes obscure the external os. The image is sometimes improved if the patient is placed in the left-side-down decubitus position.
- 5. Follow a routine when performing a standard scan of an apparently normal pregnancy. However, even with a normal pregnancy you should have a low threshold for varying from the routine. For example, if you see an excellent sonographic view of something that will later need to be documented (e.g., placenta), freeze it and record an image. (You may not get another chance.) If an abnormality is noted, document it but do not forget to complete the routine scan.
- 6. First, briefly sweep the entire uterus to check for fetal viability and gross pathology as well as to determine the direction in which the fetus is lying. For first-trimester scans, it is important to methodically sweep the entire uterus to exclude multiple gestations. After gross pathology is excluded, it may enhance bonding to allow the patient and family to watch the images during scanning.
- 7. Next, with second- and third-trimester scanning, evaluate the lower uterine segment before the bladder fills and distorts the cervical length or its relationship to the placenta.
- 8. To maintain orientation, evaluate the long axis and transverse views of the spine if the fetus is in a convenient position. After getting oriented to the fetal spine, you will be three-dimensionally oriented to how the fetus is lying (e.g., on all fours). Transverse views of various organs will then be easier to obtain and will make more sense.
- 9. Evaluate the fetus in transverse views from head to pelvis. In particular, transverse views of the brain, spine, chest, heart, diaphragm, abdomen, stomach, kidneys, and bladder should be obtained. The cord insertion site should be imaged. Record appropriate images for documentation.
- Longitudinal views of the spine, diaphragm, stomach, kidneys, and bladder should also be visualized. Record appropriate images for documentation.
- Next, evaluate the extremities. The clinician should visualize all four extremities. Record an image of a femur for measurements.
- 12. A final sweep should be made through the entire fetus and at least an informal BPP performed for late-trimester pregnancies.
- 13. Finally, the placental site and amniotic fluid volume should be evaluated. For transabdominal scanning, if the placenta has not already been visualized during the previous scanning, it is usually located posteriorly. If there has been difficulty imaging the fetus, the amount of amniotic fluid is probably reduced.
- 14. While scanning, the necessary measurements listed in the next section should be obtained. Techniques and formulas for obtaining specific measurements are also discussed in the following sections. Use the appropriate sections when attempting to answer particular clinical questions or for certain situations as needed.

# **Measurements**

**NOTE:** Newer ultrasonography machines calculate many of these values for the sonographer based on the formulas given in the text. Many also use nomograms for making estimates; estimates on age or weight are most accurate when multiple parameters are used and the nomograms have been derived from fetuses of the same ethnic or racial background living at similar altitude.

The BPD, abdominal circumference, and femur length are measured as the basis of most obstetric ultrasonographic evaluations. Early in pregnancy, CRL and gestational sac measurements are also important. Certain early developmental landmarks, if noted, may

<b>TABLE 172-1</b>	Developmental Landmarks
According to	Abdominal Ultrasonography

	<u> </u>
Landmark	Fetal Age (from LMP)
Visualization of gestational sac Embryonic pole Fetal heart motion Fetal movement Biparietal diameter measurable	5–6 wk 6–7 wk 7–8 wk 8–9 wk 12–13 wk

LMP, last menstrual period.

also provide worthwhile information for estimating gestational age (Table 172-1).

### 1. CRL

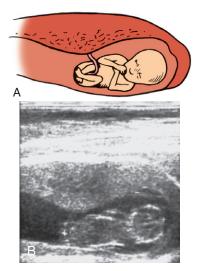

The formula is as follows:

### Gestational age (weeks) = (CRL [mm] + 65)/10

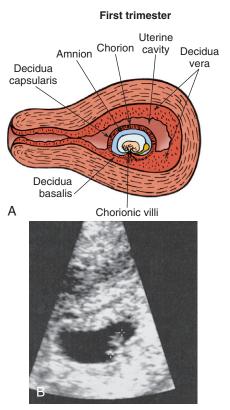

- The CRL is the longest length of the fetus in the sagittal plane and excludes the fetal limb buds and the yolk sac. One should average crown-rump measurements from three satisfactory images.
- Transabdominally, CRL is most accurate between 9 and 11 weeks. Even more accurate is CRL by transvaginal scanning between 7 and 9 weeks. The greatest problem with measuring CRL transabdominally earlier than 9 weeks is that the fetus is very small and the borders may be unclear. As a result, it may be very difficult to obtain the maximum longitudinal diameter (CRL) of the fetus. After 11 or 12 weeks, the fetus flexes and extends so much that it may be difficult to obtain the true maximal diameter (Fig. 172-2).
- 2. Gestational sac (GS) diameter
  - The formula is as follows:

# Gestational age (weeks) = (Avg GS [mm] + 25.43)/7.02

- The gestational sac measurement is not the best value to use for estimating gestational age, and it should be used only if other dating parameters are not available.
- The gestational sac consists of a hypoechogenic area, which corresponds to the chorionic vesicle, and an echogenic rim or

**Figure 172-2** Measurement of the crown–rump length. **A,** Fetus at 12 to 13 weeks. **B,** Sonogram showing the longest length of a 12-week fetus. Measurement should be made from the top of the crown (head) to the bottom of the rump.

**Figure 172-3 A,** Illustration accompanying a transvaginal photograph detailing an early gestation. The decidua capsularis and the decidua vera form the double echogenic ring. **B,** The sonogram contains a fetal pole with 7-mm crown–rump length, which corresponds to a 6-week gestation. Pregnancies earlier than 5 weeks by transabdominal scanning generally do not show a fetal pole. Usually, only a hypoechogenic area corresponding to the chorionic vesicle is seen at this age.

ring, which corresponds to the trophoblast. The gestational sac of a normal pregnancy also may be characterized by a double echogenic ring. The inner ring is the decidua capsularis plus the chorion laeve. The outer ring is the decidua vera. At the implantation site, the hyperechoic rim is thicker, and it comprises the decidua basalis and chorion frondosum (Fig. 172-3).

• The in utero presence of a normal gestational sac, complete with contents (Fig. 172-4), usually confirms an intrauterine pregnancy and indirectly excludes ectopic gestation. In some cases, however, it may be difficult to differentiate between the gestational sac seen with an early intrauterine pregnancy and the *pseudogestational sac* sometimes seen with an ectopic pregnancy (see the First-Trimester Standard Scan Documentation section, and Chapter 225, Emergency Department, Hospitalist, and Office Ultrasonography [Clinical Ultrasonography]).

**NOTE:** This method of exclusion of ectopic pregnancy may not be helpful for patients taking ovulation induction medications for fertility (see the First-Trimester Standard Scan Documentation section).

 The gestational sac is measured inside the hyperechoic rim, including only the anechoic (dark or fluid-filled) space. If the sac is round, only one dimension is needed; if ovoid, three measurements are taken and an average diameter calculated (Avg GS).

### 3. BPD

 The BPD is measured ideally when the fetus is lying in the occiput transverse position. In this position, BPD is the distance measured between the outer table of the proximal

<sup>\*</sup>Many of these may be visualized up to a week earlier with transvaginal scanning.

**Figure 172-4** Gestational sac with yolk sac on transvaginal ultrasonography. **A,** Yolk sac is generally first seen at about 5 weeks' gestation by transvaginal scanning and at 6 to 7 weeks' gestation by transabdominal scanning. Its presence confirms an intrauterine gestation but does not rule out a rare concomitant ectopic pregnancy (see text). **B,** Sonogram of gestational sac with yolk sac demonstrated.

fetal skull and the inner table of the contralateral side of the skull.

**NOTE:** The BPD is one of the only outer-to-inner diameter measurements used in all of sonography. Inner diameter is used because the posterior calvarium causes a lot of artifact and tends to distort outer-to-outer diameter measurements (Fig. 172-5).

- The most commonly accepted reference plane for BPD is a cross-section parallel to the canthomeatal line and slightly above it. This cross-sectional plane cuts through the falx cerebri, the thalamus, the cavum septi pellucidi, and the medial cerebral artery. The head shape should be oval at this plane.
- 4. Head circumference (HC)
  - The formula is as follows:

HC = 1.57 (BPD + occipital – frontal diameter [OFD]).

**NOTE:** Some clinicians use HC = 1.57 (BPD + 0.3 cm + OFD) because of the manner in which BPD is measured.

- The OFD is measured in the same plane as the BPD. The OFD diameter measurement should be made from the skull's outerto-outer aspect.
- 5. Cephalic index (CI)
  - The formula is as follows:

# CI = BPD/OFD

 Prenatal molding of the fetal skull is common and may result in an inaccurate determination of the BPD. The CI (the ratio of the BPD to the OFD) can be used to screen for cranial shape abnormalities. The CI is a constant throughout pregnancy. The normal value is 78.3% ± 8% (±2 standard deviations

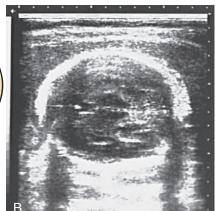

- [SD]). Values below this normal range indicate a dolichocephalic head (an ellipse with a BPD that is shorter than expected, or "too flat"). Values above this normal range indicate a brachycephalic head (an ellipse with a BPD that is wider than expected, or "too round").
- If the CI is significantly above or below the normal range, the BPD may not be a reliable estimation of gestational age.
   Instead, the HC should be used for estimating gestational age.
- 6. Abdominal circumference (AC)
  - The formula is as follows:

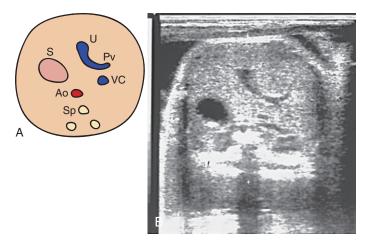

$$AC = 1.57 (D_1 + D_2)$$

- Two diameters (D<sub>1</sub> and D<sub>2</sub>), the anteroposterior abdominal diameter and the transverse abdominal diameter, are taken at the level of the stomach, the liver (if kidneys or ribs are visualized, the level is too high), and the junction of the umbilical vein and the left portal vein. This junction appears as an echolucent structure shaped like a hockey stick. These diameters should be at right angles to one another, and the plane in which they are taken should be at a right angle to the fetal spine. These measurements should also be outer-to-outer diameter measurements.
- For estimating gestational age, the AC is useful only when there is no clinically apparent maternal or fetal condition that would modify liver growth. Because it relies on measurement of soft tissues, the AC is the least accurate of these methods for estimating gestational age. That said, it is most useful for estimating gestational age in midgestation and late pregnancies (Fig. 172-6).
- 7. Femur length (FL). The central diaphysis of the shaft of the femur should be measured (not including the epiphysis), and the beam should be as perpendicular to the shaft as possible (Fig. 172-7).

**Figure 172-5 A,** Biparietal diameter (BPD) is measured from outer to inner aspects of the skull. C, cavum septi pellucidi; F, falx cerebri; T, thalami. **B,** Sonogram of the fetal cranium at the proper level for a BPD, the level of the cavum septi pellucidi and thalamus. Note artifact behind posterior skull table.

**Figure 172-6** Abdominal circumference. **A,** This third-trimester cross-section of the fetal abdomen shows the junction of the umbilical vein and left portal vein. The stomach is seen on the left side of the fetus. **B,** Cross-sectional sonogram of fetal abdomen. Ao, aorta; Pv, portal vein; S, stomach; Sp, spine; U, umbilical vein; VC, vena cava.

This is not necessarily the largest or longest measurement that can be obtained. (The longest measurement may include the femoral neck, which, if included, would overestimate the true value.)

# **Fetal Body Ratios**

- 1. Cephalic index. (See previous discussion.)
- 2. Head circumference/abdominal circumference. This ratio has a positive predictive value of 62% for detecting asymmetric IUGR and a negative predictive value of 98%. The HC/AC is normally about 1.2 at 20 weeks' gestation and drops linearly to about 1 at 36 to 38 weeks' gestation. From that time, it remains about 1 or below until delivery. Screening for an HC/AC greater than 1 after 36 weeks detects 85% of IUGRs. This method fails to detect symmetric IUGR.
- 3. Femur length/abdominal circumference. The FL/AC ratio will not detect symmetric IUGR, but it is sensitive for asymmetric IUGR. This ratio has the further advantage of having normal-range values that do not change with time after 20 weeks. The normal value for this ratio expressed as a percentage is 22% ± 2% (±2 SD). A value greater than 24% indicates IUGR. A value less than 20.5% is suggestive of macrosomia. However, even though the negative predictive value is 92% to 93%, the positive predictive value is only 18% to 20%.
- 4. Femur length/biparietal diameter. After 22 weeks' gestational age, the FL/BPD ratio is almost constant, with a normal range of 79% ± 8% (±2 SD) from 22 to 40 weeks. The predictive values of this ratio are similar to those for FL/AC. The FL/BPD has three important uses: (1) evaluation of the ultrasonographic examina-

tion for measurement error, (2) detection of diseases of the fetal head and limbs, and (3) classification of IUGR.

# **Ultrasonographic Dating**

- 1. Because of biologic variability, traditional clinical methods can estimate gestational age with 90% certainty only to within 2 weeks. This is the limit when even the best clinical methods are applied (using last menstrual period, date when uterus reaches umbilicus, first heard fetal heart tones, fundal height, and quickening). In part, this is because 25% to 45% of women are unable to provide an accurate menstrual history. For this and other reasons, the estimated date of confinement derived from the last menstrual period differs by more than 2 weeks from the actual date of birth in nearly one fourth of pregnancies. Ultrasonographic dating early in pregnancy is more accurate and can be helpful for correcting the estimated date of confinement.
- 2. Ultrasonographically determined size of certain body parts correlates with gestational age. In general, growth is quite uniform in the first 20 weeks of gestation. Thereafter, the progressive increase in variability makes estimation of gestational age difficult and less accurate (Table 172-2).
- 3. When reporting ultrasonographic estimates of age, it is very important to understand and report the associated uncertainties. The uncertainty or variability is usually expressed as plus or minus two standard deviations (±2 SD), which should be applicable to 95% of fetuses in a normal population. Reporting a single age estimate for a given fetal measurement gives a false impression about the accuracy of the method. Thus, the variability of the estimate (in SD) should be given as well.

**Figure 172-7 A,** Third-trimester femur is measured along the central shaft of the diaphysis. **B,** Sonogram demonstrating the echogenic distal femoral epiphyseal ossification center on the right, which indicates a gestational age of 33 weeks or more.

<b>TABLE 172-2</b>	Outline of	Ultrasonographic [	Dating
of Pregnancy			

Weeks of Gestation	Recommended Dating Measurement	Accuracy
3–5	None	
5–6	GS	±I wk
6–12	CRL	±3–5 days
12–20	I. BPD 2. FL	±1 wk ±1 wk
20–30	1. BPD 2. FL 3. AC	±2 wk ±2 wk ±3 wk
30–40	1. BPD 2. FL 3. AC	±3 wk ±3 wk ±3.5 wk

AC, Abdominal circumference; BPD, biparietal diameter; CRL, crown–rump length; FL, femur length; GS, gestational sac.

- 4. Pregnancy dating often uses an average of estimates of age from several methods; see Box 172-1 for suggestions as to which parameters to use with each stage of pregnancy. Any of the measurements may be technically incorrect, especially by the third trimester. However, it is unlikely that several measurements will be incorrect in the same direction. Therefore, when averages are used, measurement errors tend to be self-canceling and a more accurate overall estimate of gestational age is made. However, each measurement should be assessed individually; if one measurement is significantly different from the others, it can be excluded from the calculation.
- 5. When using the multiple-parameter dating approach, or an averaged estimate of age, it is also critical to avoid using any measurements that might have been affected by a pathologic process in the fetus (e.g., hydrocephaly, microcephaly, macrosomia, IUGR, or fetal dwarfism). After 22 weeks' gestational age, potential errors can be minimized by making certain that the fetal body ratios are within normal limits (see the Fetal Body Ratios section). If the CI indicates a normally shaped head, the FL/BPD ratio can be calculated. If the FL/BPD ratio is below 70%, the FL should be eliminated; if the ratio is above 86%, the fetal head measurements should be discarded. If the FL/BPD ratio is normal, the FL/AC ratio can be calculated. If the FL/AC ratio is less than 20%, the AC should not be used because of possible macrosomia; if the ratio is above 24%, the AC should not be used because of possible IUGR.
- 6. The presence of certain fetal epiphyseal ossification centers may be helpful when estimating gestational age for pregnancies beyond 30 weeks. This is especially useful at this stage of pregnancy because we know dating by other ultrasonographic parameters has limited reliability (see Table 172-2). A visible distal femoral epiphysis (see Fig. 172-7) indicates a menstrual age of at least 33 weeks, a visible proximal tibial epiphysis indicates a menstrual age of at least 35 weeks, and a visible proximal humeral epiphysis indicates a gestational age of at least 38 weeks.

### **Organ Survey**

- Fetal organs should be categorized as anatomically normal, abnormal, or not visualized. Among all anomalies, cardiac defects are the most common; central nervous system defects are almost as common, especially neural tube defects. Deviations from normal anatomy require a specialized scan.
- 2. The brain should be surveyed in three transverse (axial) views. The transthalamic view is used to measure BPD and HC and is at the level of the thalamus and cavum septi pellucidi. Moving slightly superiorly, with the transventricular view, the lateral

- ventricles and their atria are visualized, and this is where the echogenic choroid plexus is noted. (The atria are the confluens of the lateral and occipital horns.) The diameter of an atrium is normally between 5 to 10 mm from 15 weeks to term; ventriculomegaly is quantified by amount of dilation (>10 mm but <15 mm, mild; >15 mm, moderate to severe). Angling posteriorly through the posterior fossa produces the transcerebellar view. The cisterna magna and cerebellum are usually measured, with the cerebellar diameter in millimeters being roughly equivalent to the gestational age in weeks for up to 20 weeks (accurate enough to help establish gestational age in late registrants; tables are available for after 20 weeks).
- 3. The spine should be surveyed in its entire length in both longitudinal and transverse views. Neural tube defects result from incomplete closure by 6 weeks. In 90% of cases of spina bifida, not only is there an opening in the vertebrae through which the meninges protrude (meningocele), but the sac also contains neural elements (meningomyelocele). One or more additional defects are classically associated with spina bifida (e.g., small BPD, ventriculomegaly, frontal bone scalloping, elongation and downward displacement of the cerebellum, effacement or obliteration of the cisterna magnum).
- 4. The lungs are best visualized from 20 to 25 weeks, and they should be homogeneous. Cystic or solid lesions may need further evaluation with a specialized scan. Ninety percent of diaphragmatic hernias are located on the left side and posteriorly, and almost half are associated with other major anomalies or aneuploidy. The heart may be pushed to the middle or right side of the thorax, the stomach bubble may be missing from the abdomen, and the AC may be decreased.
- 5. The basic survey of the heart should include a four-chamber view, rate, and rhythm. The four-chamber view is obtained with a transverse view immediately above the diaphragm. The two atria should be about the same size, and likewise the two ventricles, respectively. The apex of the heart should form a 45-degree angle with the left anterior chest wall; abnormalities of axis should be followed with a specialized scan. Thirty to 40% of cardiac defects are associated with chromosomal abnormalities. An attempt should be made to evaluate the left and right ventricular outflow tracts.
- 6. The stomach is visible in 98% of fetuses after 14 weeks. Nonvisualization could be the result of various abnormalities (e.g., esophageal atresia, abdominal wall defects, diaphragmatic hernia), so ultrasonography should be repeated in a week, possibly with a specialized scan. The liver, spleen, gallbladder, and intestine are visible in many second- and third-trimester scans. After visualizing the stomach, the abdominal wall should be scanned because defects are quite common. Gastroschisis is typically located to the right of the umbilical cord insertion, and bowel herniates into the amniotic cavity. In over half of cases, an omphalocele is associated with other major anomalies or aneuploidy.
- 7. The kidneys and urinary tract should be scanned, with kidneys visualized as early as 14 weeks and almost always by 18 weeks. Renal agenesis or cysts in the kidneys (infantile polycystic kidney disease, multicystic dysplastic kidney disease) should be noted. After 16 to 20 weeks, most of the amniotic fluid is produced by the kidneys, so oligohydramnios suggests a need to carefully scan the kidneys. Conversely, a normal AFI indicates at least one urinary tract is patent and functioning. A normal renal pelvis diameter is less than 4 mm before 20 weeks; if it is enlarged, ultrasonography should be repeated at 34 weeks, and if it is greater than 7 mm at that point, neonatology should be consulted. Pyelectasis is dilation at the level of the renal pelvis, and two thirds of infants with pyelectasis greater than 7 mm will have a renal abnormality. Duplicate collecting ducts occur in 4% of the population, and the classic finding is pyelectasis of the upper pole. Reflux of the lower pole is common, so antimicrobial therapy from birth onward may reduce the incidence of urinary

tract infections. Posterior urethral valves in a male fetus will result in dilation of the bladder and proximal urethra; associated oligohydramnios portends a poor prognosis because of pulmonary hypoplasia.

# **Placental Imaging**

- 1. Maturational changes of the placenta occur in its three basic anatomic areas (the amniochorionic plate, the placental body, and the basal layer) and form the basis for the following grading system of placental maturity (Fig. 172-8):
  - **Grade 0:** Placenta has a chorionic plate that is very smooth. The placental substance is homogeneous and without calcifications.
  - **Grade I:** There is some undulation and some indentations in the chorionic plate. There are also scattered echogenic areas, which represent calcifications in the placental substance.
  - **Grade II:** The chorionic plate has more indentations, but they do not reach the basal plate. The grade II placenta is characterized by a straight line of echoes with calcifications present along the axis of the basal plate. These echoes are high-amplitude, bright, white, and linear or comma-shaped.
  - **Grade III:** The chorionic plate indentations reach the basal plate. There is complete compartmentalization of the placenta with extensive echogenic areas representing calcifications. They may cast shadows.

**NOTE:** In a third-trimester transabdominal scan, if the placenta has not been located by the time the other parameters have been obtained, it is usually located posteriorly, having been obscured by infant body parts.

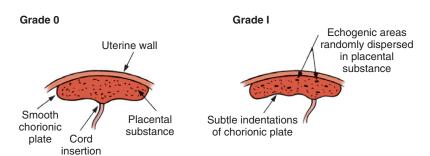

- 2. Grade 0 is most common in the first trimester; grade I appears after 14 weeks' gestation and is most common until around 34 weeks. Grade II may appear after 26 weeks' gestation and is most common at around 36 weeks. Grade III most commonly appears after 35 weeks' gestation. Even with a grade III placenta, there is a 4% chance of fetal pulmonary immaturity.
- 3. A grade II placenta before 26 weeks or a grade III placenta before 35 weeks is abnormal.
- 4. IUGR, oligohydramnios, and hypertension are associated with accelerated placental maturation. Diabetes mellitus and Rh

- sensitization are associated with delayed maturation. Preeclampsia and pregnancy-induced hypertension do not affect placental maturation.
- 5. The principal purposes of the ultrasonographic examination for bleeding in the second and third trimesters are to delineate the placental implantation site, to exclude placenta previa, and to attempt to determine whether there has been an abruption. Scanning transvaginally or transperineally may improve visualization of these abnormalities in the second and third trimester and during labor.

**NOTE:** In the proper scenario, unless a large abruptio placentae is clearly confirmed on ultrasonography, the possibility should be managed clinically (as if there is an abruptio placentae). With ultrasonography, there is a risk of false-negative findings; most placental abruptions are small and easy to miss. There is also the risk of a false-positive result; venous lakes can appear very similar to abruptio placentae.

### **Amniotic Fluid Volume**

- Estimation and documentation of amniotic fluid volume (AFV) is the standard of care during routine ultrasonographic examinations. Although there is no precise method of determining AFV, there are several indirect methods of estimation.
  - Subjective assessment: Although simple and rapid, if used alone
    a subjective assessment (e.g., increased, decreased, normal
    fluid volume) requires an experienced sonographer. Because
    the result lacks a numeric value, it is difficult to follow trends;
    therefore most centers prefer an AFI over subjective assessment for estimating AFV. That said, even if a maximal vertical pocket or AFI will be measured, clinicians should practice
    making a subjective assessment and record it.
  - Maximum vertical pocket or 2-diameter: The maximal vertical pocket technique involves measuring the single deepest vertical pocket of amniotic fluid, not including segments of the umbilical cord. Oligohydramnios is defined as the absence of a pocket of fluid at least 2 cm in depth, and polyhydramnios is diagnosed when any pocket exceeds 8 cm. This technique is most helpful for quantitating fluid with a multiple-gestation pregnancy or in the assessment of polyhydramnios. The 2-diameter method has been used in BPPs. Excluding

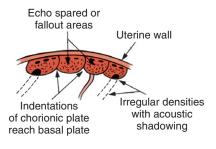

Grade II

Basal echogenic densities Uterine wall

Comma-like Indentations deeper in chorionic plate

Grade III

**Figure 172-8** Four grades of placental maturity. (Redrawn from Grannum P, Berkowitz R, Hobbins J: The ultrasonic changes in the maturing placenta and their relation to fetal pulmonic maturity. Am | Obstet Gynecol 133:915–922, 1979.)

- umbilical cord, there should be at least one pocket of amniotic fluid measuring 2 cm in both the horizontal and vertical planes (i.e.,  $2 \times 2$  cm), which results in a score of 2. Failure to identify a fluid pocket of at least this size results in a score of 0.
- Amniotic fluid index: This is the quantitative approach to estimating the AFV used by most centers. The uterus is divided into four quadrants. The ultrasound transducer is then held in a vertical and sagittal alignment (marker dot on the probe turned toward the mother's head/cephalad). With the patient supine, the transducer is held perpendicular to the plane of the floor and aligned longitudinally with the mother's spine. Starting in one quadrant, the pocket of fluid with the largest vertical dimension is identified, measured, and recorded. Care must be taken not to include segments of the umbilical cord in the measurement. Coiled cord can fill the space and appear to be fluid (color Doppler can be used to identify the cord). This procedure is repeated in each quadrant and the values summed. If the sum (AFI) is less than 8 cm, perform the fourquadrant evaluation three times and average the values. From 16 weeks onward, the majority of normal pregnancies have an AFI between 8 and 24 cm.

### 2. Polyhydramnios

- In nondiabetic women, polyhydramnios is defined as an AFI of 24 cm or more.
- The most likely etiology is idiopathic (34.6%), followed by diabetes mellitus (24.6%), congenital anomalies (20.1%), erythroblastosis fetalis (11.5%), and multiple gestation (9.2%).
- Once identified, a patient with an AFI of 24 cm or more should have a detailed or targeted ultrasonographic examination to rule out fetal anomalies.
- Abnormal fetal lie, operative delivery, and placental abruption all occur more frequently during labor in patients with polyhydramnios.

# 3. Oligohydramnios

- Significant oligohydramnios is defined as an AFI of less than 5 cm.
- Excluding patients with premature rupture of membranes, approximately 83% of patients with oligohydramnios will have fetal IUGR; however, only 16% of patients with fetal IUGR will have oligohydramnios.
- Fetal weight should be estimated whenever oligohydramnios is present.
- Premature rupture of membranes can cause severe oligohydramnios or anhydramnios.

- Fetal causes of oligohydramnios are usually related to urinary tract anomalies.
- Fetal heart rate abnormalities, depressed Apgar scores, and passage of meconium all occur more frequently during labor in patients with oligohydramnios.
- In most cases, oligohydramnios in a term infant is an indication for delivery.

# Fetal Assessment (Biophysical Profile)

- 1. A combination of biophysical variables (the BPP) was first introduced by Manning in 1980. The most important aspect in the sensitivity of this test is that it combines both acute and chronic markers of the fetal and placental condition (Table 172-3). Documenting the acute markers (fetal heart rate reactivity [FR; normal is reactive on nonstress test], fetal movement [FM; normal is three or more significant body or limb movements in 30 minutes], fetal breathing movement [FBM; normal is 30 seconds or more of breathing movements in 30 minutes], and fetal tone [FT; normal is extension/flexion of an extremity or spine and then return to normal position]) is very similar to performing an in utero neurologic examination of the infant. It can demonstrate acute oxygenation of various parts of the neurologic system. Normal acute markers result in a score of 2 each; abnormal, a score of 0. Documenting the chronic marker (AFI) is similar to obtaining a "hemoglobin  $A_{1C}$ " of fetal oxygenation; it demonstrates how well the fetus has been oxygenated over the past few days, weeks, or maybe even a month. Normal AFI, maximal vertical pocket, or a 2-diameter pocket results in a score of 2. Failure to identify a 2-diameter fluid pocket (one at least 2 × 2 cm in diameter) results in a score of 0. Conversely, even if there is oligohydramnios using an AFI (i.e., AFI <5 cm), if there is a  $2 \times 2$ -cm diameter pocket, the score for BPP is 2. Adding the acute and chronic markers, the highest possible score for a normal fetus is 10.
- 2. A normal BPP is indirect evidence that each of the portions of the central nervous system that control particular activities is functioning and, therefore, oxygenated. When all of the various portions of the central nervous system are active, it indicates that overall the fetus is well oxygenated at that time. The absence of a given BPP activity, however, is difficult to interpret because it may reflect either pathologic depression or normal periodicity.
- In chronic sustained fetal hypoxia, a protective redistribution of fetal cardiac output may occur, with blood being directed away from nonvital fetal organs (kidneys or lung) toward vital fetal

TABLE 172-3 Fetal Biophysical Profile (BPP) Scoring				
Variable	Score 2	Score 0		
Fetal breathing movement (FBM)	The presence of at least 30 sec of sustained FBM in 30 min of observation	<30 sec of FBM in 30 min		
Fetal movement	Three or more gross body movements in 30 min of observation; simultaneous limb and trunk movements are counted as a single movement	Two or fewer gross body movements in 30 min of observation		
Fetal tone	At least one episode of motion of a limb from a position of flexion to extension and a rapid return to flexion	Fetus in a position of semi- or full-limb extension with no return to flexion with movement; absence of fetal movement is counted as absent tone		
Fetal reactivity*	The presence of two or more fetal heart rate accelerations of at least 15 bpm and lasting at least 15 sec and associated with fetal movement	No acceleration or less than two accelerations of the fetal heart rate during observation (see Chapter 165, Antepartum Fetal Monitoring)		
Qualitative amniotic fluid volume <sup>†</sup>	A pocket of amniotic fluid that measures at least 2 cm in two perpendicular planes	Largest pocket of amniotic fluid measures <2 cm in two perpendicular planes		
Maximal score	10	_		
Minimal score	_	0		

<sup>\*</sup>Most centers perform a nonstress test.

<sup>&</sup>lt;sup>†</sup>Most centers usually determine an amniotic fluid index.

Updated from Manning FA, Platt LD, Sipos L: Antepartum fetal evaluation: Development of a fetal biophysical profile. Am | Obstet Gynecol 136:787–795, 1980.

- organs (heart, brain, and adrenals). This redistribution leads to decreased renal perfusion and urine production, oligohydramnios, and a low AFI. A low AFI may be the earliest marker of placental insufficiency.
- 4. A fetal BPP score of 8 or more is reassuring of fetal well-being; a BPP of less than 8 is nonreassuring, and repeated testing or delivery is indicated (see Table 172-3). The presence of oligohydramnios constitutes an abnormal biophysical assessment regardless of the overall score.

### **Fetal Size**

- Many formulas and tables are available for prediction of fetal weight. These formulas are based on a variety of combinations of BPD, HC, AC, and FL. The predictive accuracy of these formulas ranges from ±14.8% to ±20.2% (±2 SD). Formulas are often compared against a commonly used table (Shepard and colleagues, 1987).
- 2. On clinical examination, a discordance between size and dates should arouse suspicion of specific disorders, depending on gestational age. In early pregnancy, suspect multiple gestation, a hydatidiform mole, incorrect menstrual history, and genetic or developmental defects. Later in pregnancy, fetal malposition, IUGR, fetal dysmaturity, genetic or developmental defects, multiple gestation, fetal macrosomia, and abnormal AFV are causes to consider. Many of these possibilities can be further evaluated with ultrasonography.

### Intrauterine Growth Retardation

- 1. Clinical signs of IUGR include poor increase in fundal height (>4 cm difference from expected fundal height) or maternal weight gain (<100 to 200 g [3.5 to 7 oz] per week in third trimester), or both. However, diagnosis of IUGR by clinical means is possible in only about 33% of pregnancies.
- 2. By comparison, a diagnosis of IUGR by ultrasonography is much more accurate, especially if dating is accurate (e.g., from transabdominal ultrasonography at 9 to 11 weeks). However, even with ultrasonography, sensitivities and specificities are variable, so ultrasonographic information should be correlated with clinical data. This combination of information will significantly improve a clinician's ability to diagnose IUGR.
- The following are important ultrasonographic parameters for evaluating potential IUGR.
  - Oligohydramnios
    - For the general population, the sensitivity of oligohydramnios in the diagnosis of IUGR is approximately 16%.
    - For high-risk populations, the predictive value and sensitivity of oligohydramnios are enhanced (sensitivity can exceed 85%). If oligohydramnios is present and there is no evidence of premature rupture of membranes or congenital anomalies, IUGR is the likely cause. The combination of oligohydramnios and IUGR portends a less favorable outcome, and early delivery should be considered. Generally, if the pregnancy is at 36 weeks or more, the high risk of intrauterine loss may mandate delivery.
  - Biparietal diameter. BPD alone is not a very helpful parameter when diagnosing IUGR; however, it is useful for ratios. With symmetric IUGR, both head and body measurements fall off the growth curve together and result in an erroneous estimate of gestational age. Even with asymmetric IUGR, the BPD remains normal until late in the course.
  - Head circumference. The HC is a more shape-independent measurement of fetal head size than the BPD. In cases of cranial shape abnormalities, its inclusion in the growth profile will significantly decrease the high number of false-positive results seen when BPD is used. However, because IUGR may not selectively affect brain and head growth, or is "relatively head-sparing," HC alone is also not a very useful measure-

- ment. The HC is most useful when it is used with another measurement as a ratio.
- Femur length. The FL can also be misleading when trying to diagnose IUGR. In asymmetric IUGR, FL usually parallels the gestational age as calculated from the last normal menstrual period. Therefore, for asymmetric IUGR, FL may not be helpful. In symmetric IUGR, all measurements will be small and result in an erroneously early gestational age estimate, so again FL is not helpful. Similar to HC, FL is most useful for prediction of IUGR when it is used in a ratio.
- Abdominal circumference. The AC is useful for assessing fetal nutritional status. The AC involves measurement of the liver, which is smaller in chronic hypoxia. With inadequate oxygen or nutrition, the liver cannot produce substrate (glycogen); thus the AC is the best single predictor of IUGR.
- Calculation of fetal body ratios (see the Fetal Body Ratios section).
- Placental grade. When fetal growth pattern and estimated weight suggest a small fetus, the finding of a prematurely grade III (before 35 weeks) placenta is further evidence of IUGR.
- Use of fetal epiphyseal ossification centers (see the Ultrasonographic Dating section).
- 4. Suspect IUGR by ultrasonography if the following occur:
  - AC falls in the lower 15th percentile. (Sensitivity of ultrasonography is >95% if AC <2.5th percentile.)</li>
  - Weight falls in the lower 15th percentile.
  - HC/AC ≥0.95 (HC/AC >1.0 after 36 weeks detects 85% of IUGR).
  - FL/AC ≥23.5%.
- 5. In the absence of an accurate gestational age, the assessment of risk for IUGR relies predominantly on fetal disproportionality and asymmetry. This may lead to the diagnosis of asymmetric IUGR. However, to diagnose symmetric IUGR, unless dates are very accurate, serial ultrasonographic studies must be performed to assess fetal growth. Some experts recommend serial scans at 2- or 3-week intervals to identify IUGR in the absence of reliable dating. Therefore, for those at risk, liberalizing the use of early ultrasonography for establishing gestational age may be the best way to diagnose symmetric IUGR.
- 6. Newer techniques to identify IUGR are being evaluated, including Doppler velocimetry of the umbilical artery or other placental vessels and M-mode echocardiography of the fetal heart. Abnormal placental vessel Doppler velocimetry may alert the clinician to the need for an additional study such as a BPP, continuous fetal monitoring, or delivery.

### Macrosomia

- Fetal macrosomia is defined in absolute terms as a fetal weight of greater than 4000 g, regardless of gestational age. However, macrosomia is also considered when a fetal weight falls in the upper 90th percentile for any gestational age at any point during the pregnancy.
- 2. Symmetric macrosomia occurs when the excessive fetal weight is the result of proportionate growth of all fetal parameters. For example, the weight, length, and head size may all be above the 90th percentile for age. Symmetric macrosomia is usually the result of a prolonged gestation or genetics (i.e., large parents). The HC/AC and the FL/AC ratios are usually within the normal range for age.
- 3. Asymmetric macrosomia generally occurs in patients with class A to C gestational diabetes mellitus. Although the values of HC and FL are higher than average, they usually fall below the 90th percentile for age. The excessive weight results from profound increases in soft tissue mass that are reflected by an AC and an estimated fetal weight above the 90th percentile. The HC/AC and the FL/AC ratios usually fall below the 10th percentile for age.

**NOTE:** Sonographic diagnosis of macrosomia does *not* predict prognosis for vaginal delivery, largely because the positive predictive rate for macrosomia in postdates pregnancies is only about 50%. In fact, for suspected macrosomia, the accuracy of estimated fetal weight by ultrasonography is no better than that obtained with clinical palpation (Leopold's maneuvers). As a result, ACOG guidelines (November 2000) state that suspected macrosomia is not a contraindication to attempted vaginal birth. However, they do state that prophylactic cesarean delivery may be considered with estimated fetal weights of more than 5000 g in women without diabetes and more than 4500 g in diabetic women.

#### **Preterm Labor**

- 1. Preterm labor is defined as onset of labor before a gestational age of 37 weeks. Preterm labor affects 10% of pregnancies and accounts for 75% of perinatal morbidity and mortality.
- 2. Ultrasonographic parameters that are important when evaluating the patient in preterm labor include the following:
  - Fetal number. Multiple gestations have an increased risk of preterm labor.
  - Estimated fetal weight. Preterm labor is associated with IUGR.
  - Amniotic fluid index. Preterm labor is associated with both oligohydramnios and polyhydramnios.
  - BPP score. A low BPP score may contraindicate tocolysis.
  - Other possible contraindications to tocolysis Fetal malformations.
  - Evidence of concealed placental abruption.
  - Ultrasonographic cervical evaluation
    - Cervical shortening (present if the distance from internal os to external os [or the leading edge of the portio vaginalis] is <3 cm). Transperineal and transvaginal scanning appear to be equally accurate for making this measurement. Transvaginal scanning does not seem to increase the risk of infection in women with preterm premature rupture of membranes. A cervical length of less than 2 cm or funneling (dilation and shortening of the upper half of the cervix) has been associated with a short time-interval between rupture of membranes and delivery.
    - Dilation of the endocervical canal (present if the maximal diameter of the endocervical canal exceeds 1 cm).
    - Bulging of the fetal membranes into the endocervical canal (conical or funnel-shaped rather than flat or slightly rounded shape of the internal os).
    - Thinning of the lower uterine segment (anterior wall thickness <0.6 cm).
- 3. Although studies have shown variable results with the use of cervical cerclage for cervical incompetence, at least one large prospective study found that fewer women delivered before 32 weeks if a cerclage was placed in those with a cervical length of 15 mm or less at 23 weeks.

# **Postdates Pregnancy**

- 1. Expected date of confinement is defined as 40 weeks (280 days) from the first day of the last normal menstrual period, or 266 days after ovulation, provided cycles are regular and occur at 28-day intervals. Normal term ranges from 38 to 42 weeks.
- 2. A postdates pregnancy is one with a duration that has exceeded 42 weeks (294 days) from the last normal menstrual period, assuming a 28-day cycle.
- 3. One study showed that the incidence of postdates pregnancy was overestimated by 7.5% when gestational age was determined using just the menstrual history, but it fell to 2.6% with early ultrasonographic examination, and to 1.1% when both menstrual history and early ultrasonographic measurements were used.
- 4. Complications detectable by ultrasonography include the following:

- Physiologic oligohydramnios (these are detectable by AFV determination).
- Macrosomia (this is detectable by calculation of estimated fetal weight).
- Dysmaturity resulting from chronic uteroplacental insufficiency (this is detectable by evidence of asymmetric IUGR).
- Congenital anomalies (these are detectable by anatomic survey).
- Inaccurate dating (e.g., a preterm delivery could be prevented by having good estimates of gestational age).
- 5. The contraction stress test (CST) is still regarded as the most reliable method of antenatal surveillance for a postdates pregnancy. However, it has basically been replaced by the modified BPP (nonstress test [NST] combined with an AFI) or the BPP (which usually includes an NST). Studies comparing the use of twice-weekly modified BPP or BPP with a CST do not show a significant difference between the tests (see Chapter 165, Antepartum Fetal Monitoring). All are characterized by minimal morbidity and mortality but unfortunately high intervention and cesarean section rates. The benefits of obtaining twice-weekly modified BPP over the other techniques include the fact that a sonographer or physician is not required to perform a modified BPP. Specially trained personnel (nursing) are certainly capable of performing these two evaluations.

# First-Trimester Scanning

See Chapter 225, Emergency Department, Hospitalist, and Office Ultrasonography [Clinical Ultrasonography], for a detailed description.

- 1. Caution should be used in making the presumptive diagnosis of a gestational sac in the absence of a yolk sac or a definite embryo. Therefore, this portion of the study deserves special attention. It is very easy to overlook a second or third gestational sac in first-trimester scans, and this is the most common time that one is overlooked. This is also the best time to determine the number of chorions for multiple gestations (monochorionic twins are at higher risk for complications such as cord entanglement).
- First-trimester scanning is the best opportunity to evaluate the uterus (including the cervix), adnexa, and cul de sac for abnormalities.
- 3. The most common causes of bleeding in the first trimester include the following:
  - Unknown causes
  - Embryonic resorption/ blighted ovum
  - Threatened, missed, incomplete, or complete abortion
  - Ectopic pregnancy
  - Abortion of one member of a multiple gestation
  - Hydatidiform mole
- 4. Transvaginal scanning is preferred at this gestational age; color flow and Doppler should generally be avoided (there are few clinical uses and the ultrasonic "dose" is higher). When evaluating for ectopic pregnancy by transabdominal scanning, an extrauterine gestational sac is seen in less than 10% of cases (rates are higher with transvaginal scanning). Ultrasonography is more helpful for excluding ectopic pregnancy by demonstrating an intrauterine gestation. When an intrauterine gestation is clearly demonstrated, the likelihood of simultaneous extrauterine and intrauterine gestations (i.e., a combination pregnancy) is only 1 in every 7000 to 8000 cases or 1 in 30,000 low-risk pregnancies. If a patient has had infertility treatment, the risk of a heterotopic pregnancy increases and must be considered.

An ectopic pregnancy becomes almost certain with transvaginal scanning if (a) there is no intrauterine pregnancy, (b) the patient has no vaginal bleeding, and (c) the quantitative human chorionic gonadotropin (hCG) is more than 2000 IU.

- 5. The sonographic appearance of a gestational sac can be simulated by the exfoliation of hyperplastic endometrium associated with an ectopic pregnancy. This sonographic finding, known as a *pseudogestational sac*, can appear very similar to a gestational sac. A pseudogestational sac occurs in 10% to 20% of ectopic pregnancies. Thus, the unequivocal diagnosis of an intrauterine pregnancy should not be made until the gestational sac contains two concentric rims, a fetal pole, and a yolk sac, or fetal heart activity can be identified within the sac.
- In a normal pregnancy, the mean serum hCG doubling time is 1.98 days. If serial hCG titers show a plateau or fall, an abnormal (ectopic) or nonviable pregnancy is likely.
- 7. There are many reasons variations can exist between institutions when measuring hCG. Purity differences among test kits (different manufacturers) can contribute to variations in measurement. Variations can even exist in the same laboratory in different runs, or occasionally in the same run. With this much variation, even using a given standard, it is important to be aware which test kit is being used when correlating the sonographic findings with the quantitative hCG levels.
- 8. Optimally, each institution should correlate its ultrasonography equipment and sonographers' skill with quantitative hCG levels obtained from its own reference laboratory. When this is accomplished, externally published quantitative hCG reference levels and expected ultrasonographic findings should be used only as rough guidelines. Current published quantitative hCG levels and ultrasonographic correlations are outlined in Table 172-4.
- 9. If a gestational sac is absent at an hCG value above the institution's threshold, ectopic pregnancy, recent spontaneous abortion, and early hydatidiform degeneration should be considered. Suspicion of an ectopic pregnancy should be even higher if there is significant fluid in the cul de sac.
- 10. Ultrasonographic examination can be very helpful for evaluating whether tissue is remaining after a spontaneous abortion, for diagnosing the vanishing twin syndrome (abortion of one member of a multiple gestation), and for establishing fetal viability in threatened abortion. It is the procedure of choice for evaluation of gestational trophoblastic disease.
- 11. With ultrasonographic examination alone, a normal gestational sac can often be distinguished from an abnormal sac doomed to miscarriage, even before the embryo is visible. The size and appearance of the gestational sac should be evaluated according to major and minor criteria for normality. A gestational sac of abnormal size or appearance correlates highly with an abnormal outcome.
  - Major criteria for a normal-appearing gestational sac
     A sac of 25 mm or more in diameter must reveal an embryo
     within it (17 mm in diameter for transvaginal scanning).
     The sac must be round.

- Minor criteria for a normal-appearing gestational sac
   The gestational sac is located in the fundus of the uterus.
   A thick, echogenic decidual ring surrounds the gestational sac.
  - There is evidence of the double-ring sign.
- 12. When a gestational sac with a mean diameter greater than 25 mm (17 mm for transvaginal scanning) lacks an embryo or when the gestational sac is grossly distorted, abnormal pregnancy is almost certain. Using these criteria, 76% of abnormal pregnancies and 93% of normal pregnancies will be correctly classified by only one ultrasonographic scan. Failure to meet any single major criterion or all three minor criteria will identify 53% of abnormal pregnancies but will be 100% specific in predicting spontaneous abortion.
- 13. Once embryonic cardiac motion is seen on ultrasonography, the likelihood of spontaneous abortion is very low (<16% for pregnancies less than 8 weeks; <2% to 4% after 12 weeks).
- 14. Nuchal translucency is the maximum thickness of the subcutaneous translucent area between the skin and soft tissue that overlies the fetal spine in the sagittal plane at the neck. It can be accurately measured between 11 and 14 weeks; with several large studies (e.g., N >8500, N >33,000) detecting 85% of cases of Down syndrome by ultrasonography combined with serum markers, ACOG has recognized it as an acceptable option to screen for trisomy 18 and 21.

# Intrapartum Scanning

1. Limited scans can usually be performed by individuals with minimal training in ultrasonography to document fetal life, number, and presentation, to estimate the amount of amniotic fluid, and to record the placental location and determine its relationship to the internal cervical os. However, several factors unique to late pregnancy and labor may make such scanning more difficult (e.g., physical crowding due to advanced gestational age, the low station during labor, loss of the acoustic window due to fluid loss after rupture of membranes). That said, fetal life is usually documented by observing fetal cardiac motion. It can also be documented on a still image by performing an M-mode tracing. Diagnosis of fetal demise is discussed in detail in Chapter 225, Emergency Department, Hospitalist, and Office Ultrasonography [Clinical Ultrasonography]. Fetal lie is defined by the orientation of the fetal spine to the maternal spine (longitudinal, transverse, oblique). After several sweeps of the uterus with ultrasonography. the fetal lie and presentation are usually apparent. If the fetal lie is transverse, it is helpful to know if the fetal spine is up or down in relation to the lower uterine segment because the choice of uterine incision for cesarean may be affected (risk of cord prolapse increases if the spine is up). Methods of estimating AFV are discussed elsewhere. Often the placenta is located when

# **TABLE 172-4** Possible Outcomes Based on Ultrasonography and Quantitative Human Chorionic Gonadotropin Correlations

hCG Level (mIU/mL)*	Presence/Absence of GS on TAUS	Significance
>1800	+GS	Intrauterine pregnancy; if fetal pole or yolk sac is identified, no further ultrasound is required. Ectopic pregnancy is basically ruled out. (<1:7000 risk unless patient taking fertility ovulation induction medications; see text).
<1800	+GS	Failed intrauterine pregnancy or absorbed pregnancy; ectopic pregnancy with pseudogestational sac; or very rarely, an early pregnancy that may continue.
>1800	–GS	Suspect ectopic pregnancy.
<1800	−GS	Indeterminate. May be result of an early intrauterine pregnancy, or ectopic or failed pregnancy. Follow hCG titer every 2 to 4 days; for normal pregnancies, hCG should double. However, normal hCG trends occur in 15% of ectopic pregnancies. Thus, as soon as the level crosses the threshold for the practitioner's facility, repeat the ultrasonographic examination.

GS, gestational sac; TAUS, transabdominal ultrasonography.

<sup>\*</sup>Actual values will vary from institution to institution based on particular assay used, quality of TAUS machine, and the skill of the ultrasonographer.

- performing other parts of an intrapartum scan. If not, it is probably posterior; however, uterine contractions can alter the apparent location, thickness, and appearance of the placenta. A more thorough evaluation of the placenta usually requires more comprehensive training.
- 2. Extended applications (require more training) of intrapartum scanning include examination for placenta previa or abruptio placentae (see section on Placental Imaging), evaluation of the cervix in preterm labor or for incompetent cervix (see section on Preterm Labor), evaluation for procedural guidance (see appropriate chapters), and evaluation for intrapartum twin management. Such applications may also include organ survey and biometry for fetal age and weight (see sections on Ultrasonographic Dating, Organ Survey, Fetal Size, and Postdates Pregnancy). When evaluating for placenta previa, make sure the maternal bladder is not overdistended, which can compress the lower uterine segment and cause the appearance of a placenta previa. Such scanning is probably best performed with the bladder partially full and then with an empty bladder. It should also be performed between contractions, if at all possible.
- 3. When managing intrapartum twins, the initial presentation and lie of the fetuses should be determined. After delivery of the first twin, the cardiac rate and rhythm of the second twin should be observed. Using a technique similar to external cephalic version (see Chapter 167, External Cephalic Version), guide the second twin into the cephalic presentation for delivery.

### **COMPLICATIONS**

Although there are theoretical risks of ultrasound damaging human fetuses, no proven harm has been documented to any human fetus or mother. The only other possible complications from obstetric ultrasonography are failure to diagnose an anomaly or condition, an inaccurate estimate of gestational age or weight, inappropriate reassurance of a perfect infant, or inaccurate determination of the sex of the infant. Because fetal anomalies can remain undetected even by the best sonographer with the best equipment, the patient should never be unequivocally assured that the fetus is "fine." However, the patient can be reassured with answers to certain specific questions provided by the scan.

# **POSTPROCEDURE PATIENT EDUCATION**

If follow-up scans or other management will be needed, the patient must know when and where to go for them.

# **PATIENT EDUCATION GUIDES**

# PARACERVICAL BLOCK

Scott T. Henderson

A paracervical block anesthetizes the paracervical (Frankenhäuser's) ganglion. By injecting local anesthetic submucosally into the fornix of the vagina (i.e., cervicovaginal junction), anesthesia during the first stage of labor can be attained. Although a paracervical block should enhance the experience, the pudendal nerves are not blocked. Therefore, additional anesthesia may be required for delivery. These anesthetics are also fairly short acting, so the procedure may need to be repeated during labor. This procedure is rarely used because of the availability of other techniques for regional analgesia during the first stage of labor and the potential for postparacervical block fetal bradycardia. A paracervical block can also be used for anesthesia for other procedures involving the cervix (e.g., cryosurgery, ablation, conization, loop electrosurgical excision procedure [LEEP], dilation and curettage).

### **ANATOMY**

During the first stage of labor, pain is due to increased intrauterine pressure and cervical dilation. The pain arises from the visceral sensory nerve fibers of the uterus, cervix, and upper vagina, passes through the paracervical ganglion to the hypogastric and then the preaortic plexuses, and then enters the spinal cord at T10-T12 and L1. These same fibers carry pain during a cervical procedure in the nongravid patient.

### **INDICATIONS**

- First stage of labor
- Cervical ablation or conization procedures
- Dilation and curettage
- Possibly with endometrial biopsy and intrauterine device insertion

### **CONTRAINDICATIONS**

### **Absolute**

- Uteroplacental insufficiency
- Preexisting fetal distress
- Nonreassuring fetal heart tracing
- Delivery appears imminent
- Allergy to anesthetic agent
- Presence of local infection

# Relative

 Known coagulopathy or anticoagulant therapy (e.g., heparin or its analogs, warfarin, clopidogrel [Plavix])

# **EQUIPMENT AND SUPPLIES**

- 10-mL syringe (with finger rings if available; otherwise a plain syringe can be used)
- Iowa trumpet with a 6-inch, 20-gauge needle (a must during labor; or a 3-inch needle extender on the end of a syringe with a 1½-inch, 22-gauge needle
- Anesthesia
  - Gravid: lidocaine (Xylocaine or generic) 1% (10 mg/mL) without epinephrine, or chloroprocaine (Nesacaine or generic) 1% (10 mg/mL). (Note with lidocaine that toxicity may occur with doses >1 mg/kg [70 mg or 7 mL in a 70-kg patient].) With lidocaine or chloroprocaine, toxicity can occur with rapid absorption or with intravascular administration. With lidocaine, maximum dosage should not exceed 4.5 mg/kg or a maximum of 30 mL of a 1% solution (300 mg), and maximum dose should not be repeated in less than 2 hours. With chloroprocaine, maximum recommended dose is 120 mg, and it should not be repeated in less than 1 hour.
  - Nongravid: up to 2% lidocaine or chloroprocaine can be used, with maximum recommended dose of 300 mg lidocaine or 120 mg chloroprocaine.
  - Gravid or nongravid: bupivacaine (Marcaine or generic) is contraindicated because of an increased risk of cardiotoxicity.
- Sterile gloves
- Antibacterial solution and sterile gauze pads
- Sterile ringed forceps
- Sterile speculum
- Sterile tenaculum for nongravid cervix
- Fetal heart monitor (for gravid patient)

### PREPROCEDURE PATIENT EDUCATION

Obtain informed consent and outline the possible complications, risks, benefits, and alternatives to anesthesia. (See the sample patient education and patient consent forms online at www.expertconsult.com.)

# **TECHNIQUE**

- 1. Place the patient in the lithotomy position. Observe universal blood and body fluid precautions during this procedure.
- 2. In the gravid patient, assess the cervix and proceed if dilation is 5 to 9 cm. If the cervix is dilated greater than 7 or 8 cm, proceed with caution to preclude injecting the fetal scalp.
- 3. Some clinicians swab the injection sites in the vaginal fornix with antibacterial solution—soaked sterile gauze pads, held in ringed forceps, before the procedure. For a conization procedure, some clinicians prepare the entire perineal area with an

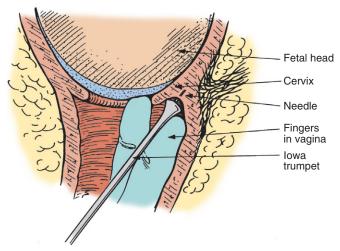

Figure 173-1 Technique of administering a paracervical block during labor using an lowa trumpet.

- antibacterial solution, as for gynecologic surgery, and then swab the injection sites in the fornix with antibacterial solution—soaked sterile gauze pads held in ringed forceps.
- 4. Using your sterile-gloved, lubricated index and middle fingers as a guide, lay the trumpet against them and insert it into the vagina (Fig. 173-1). For a nongravid cervix, paracervical block is usually performed under direct visualization, using the sterile speculum and a tenaculum placed on the anterior lip of the cervix (Fig. 173-2).
- 5. Place the 20-gauge needle within the trumpet (or 1½-inch needle on an extender) through the mucosa at the *cervicovaginal junction* at the 3 o'clock position. Take great care not to inject yourself. Also take care not to insert the needle deeper than 0.5 cm into the tissue (see Fig. 173-1). Note that in the nongravid cervix and in early labor, the nerves are located at the 4 and 8 o'clock positions, respectively (see Fig. 173-2). As labor progresses, the position of the paracervical nerves "migrates" anteriorly during progressive dilation.
- 6. After aspirating for blood (to avoid intravascular injection), inject 5 to 10 mL of the chosen local anesthetic for the gravid cervix. (Alternatively, 2 to 3 mL may be placed in two or three locations around the probable location of the nerve.) After aspi-

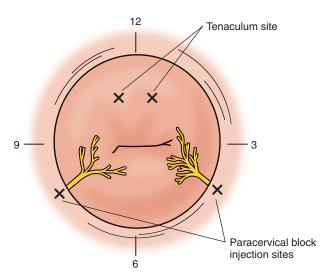

Figure 173-2 Paracervical block location in nongravid or early-labor patient and where to place the tenaculum in the nongravid cervix.

- rating for blood in the nongravid cervix, some clinicians inject at four locations, at the 3, 6, 9, and 12 o'clock positions. Because there is no risk to a fetus, they inject 10 to 15 mL of a 2% solution in each site. Others inject in multiple locations in a cufflike fashion around the cervix.
- 7. For the gravid patient, monitor the fetal heart rate for approximately 5 minutes. If the tracing is reassuring (e.g., no apparent bradycardia), inject on the contralateral side at the 9 o'clock position (or the 8 o'clock position in early labor). Then monitor the fetal heart rate for 20 to 30 minutes, along with maternal blood pressure and pulse. In the nongravid patient, if there is no untoward reaction to the first injection, repeat the injection in the previously indicated location(s).

### **COMMON ERROR**

Failure to inject at proper locations, and therefore not gaining maximum effect, is the most common error.

# **COMPLICATIONS**

- Intrafetal injection.
- Postparacervical block fetal bradycardia. This may occur in 10% to 20% of blocks. This usually occurs within 10 minutes and may last up to 30 minutes. Most studies report only a small to moderate decrease in fetal heart rate of short duration (<10 minutes). Some investigators suggest that the fetal bradycardia associated with this procedure is not a sign of fetal asphyxia because it is almost always transient and the infants are usually vigorous at birth. However, there have been occasional reports of profound bradycardia, low fetal scalp pH, depressed Apgar scores, and other adverse outcomes, including fetal demise.
- Subgluteal, paracervical, parametrial, or retropsoas hematoma or infection.
- Neuropathy resulting from hematoma formation or direct sacral plexus trauma.
- Cardiotoxicity or neurotoxicity resulting from intravascular injection.
- Allergic reactions (rare).

### POSTPROCEDURE MANAGEMENT

Continue to monitor the fetal heart rate after placing the block. It may be necessary to repeat the entire procedure, depending on the duration of activity of the anesthetic agent. A good response is generally maintained for 45 to 75 minutes. However, the effect may last only 30 minutes, or it can last as long as 90 minutes.

The patient should know to report any significant signs or symptoms of a complication after the procedure. Major late complications include a hematoma or infection, so the patient should report any fever, areas of numbness, vaginal bleeding, or abdominal, vaginal, or pelvic pain in the weeks after the procedure.

# PUDENDAL ANESTHESIA

John J. Andazola • Dolores M. Gomez

Pudendal nerve anesthesia is a common nerve block technique used in obstetrics and minor gynecologic surgery. Its advantages include its safety, ease of administration, and rapidity of onset. Pudendal nerve block can be used to provide analgesia during the second stage of labor and to facilitate pelvic floor relaxation when using low forceps and vacuum extraction. It also provides anesthesia for the perineum in order to create or repair an episiotomy. Pudendal nerve anesthesia can be used for minor surgery of the lower vagina and perineum. Epidural anesthesia has largely supplanted the use of pudendal nerve anesthesia, but pudendal blocks are an alternative when neuraxial blockade is not feasible, not effective, or contraindicated. Although both transperineal and transvaginal approaches for pudendal blockade are options, the transvaginal approach is more practical and used most often. Therefore, only the transvaginal approach is discussed here.

#### **ANATOMY**

The pudendal nerve supplies both sensory and motor innervation to the perineum. It is composed of parts of the second, third, and fourth sacral nerves and has three branches. In a woman, these branches supply the following structures:

- 1. The dorsal nerve of the clitoris, which innervates the clitoris and its erectile tissues
- 2. The perineal nerve, which innervates the muscles of the perineum and the skin of the labia minora, labia majora, and vestibule
- 3. The inferior hemorrhoidal nerve, which innervates the external sphincter of the anus and perianal skin (responsible for the anal "wink" reflex)

Pudendal anesthesia attempts to block the nerve as it enters the lesser sciatic foramen, usually inferior and medial to the insertion of the sacrospinous ligament on the ischial spine. The pudendal vessels lie lateral to the nerve at this location, so care must be taken to avoid intravascular injection. Although total block of the pudendal nerve should abolish pain and sensation over this entire area, there are other nerves that may also supply the sensory innervation to the perineum. Thus "skip" areas of analgesia may be noted, and complete nerve blockade can be ineffective on one or both sides as frequently as 50% of the time.

# **INDICATIONS**

- Obstetric anesthesia for spontaneous vaginal delivery, episiotomy and episiotomy repair, repair of low vaginal lacerations, and low (outlet) forceps or vacuum-assisted delivery
- When epidural anesthesia is incomplete or inadequate
- For minor surgery of the lower vagina and perineum

**NOTE:** Because the upper vagina, cervix, and uterus receive separate innervation from the lower thoracic nerves, pudendal anesthesia alone is insufficient for midforceps application or for high vaginal, cervical, or uterine manipulation or repair.

### **CONTRAINDICATIONS**

#### **Absolute**

- Patient refusal
- Allergy to local anesthetic agents
- Current infection in the ischiorectal space or neighboring structures, including the vagina and perineum

### Relative

Coagulopathy or anticoagulant therapy (e.g., warfarin, heparin or its analogs) or antiplatelet therapy (clopidogrel [Plavix]) is a relative contraindication for this procedure.

# **EQUIPMENT AND SUPPLIES**

- Local anesthetic: 1% lidocaine (Xylocaine or generic) without epinephrine or 1% or 2% chloroprocaine (Nesacaine or generic; this may have lower toxicity than lidocaine but does not last as long)
- Iowa trumpet (Fig. 174-1A) or similar guide to facilitate placement of the needle
- 10-mL syringe with finger ring (Fig. 174-1B)
- Needle, usually 6-inch, 22-gauge (see Fig. 174-1B) (The operator should check, before the procedure, that the needle is longer than the guiding device and equipped with a "stop" to prevent penetration of tissue deeper than 10 to 15 mm.)
- Sterile gloves

### **PRECAUTIONS**

Care must be taken to avoid intravascular injection because the pudendal vessels lie lateral to the pudendal nerve. Toxicity may occur with 1% lidocaine without epinephrine (10 mg/mL) above 1 mg/kg (70 mg or 7 mL in a 70-kg patient) with intravascular administration. Maximum dosage should not exceed 4.5 mg/kg or a maximum of 30 mL of 1% solution (300 mg), and the maximum dose should not be repeated in less than 2 hours (see Chapter 4, Local Anesthesia, for maximum dosages). A successful pudendal block may impair some reflexive maternal pushing, which may prolong the second stage of labor in women who are ineffective at pushing.

# PREPROCEDURE PATIENT PREPARATION

Explain the potential risks (see the Contraindications and Complications sections) and the potential benefits to the patient so she may make an informed decision. This discussion should include alternatives and occur before the moment of greatest anesthetic need, when neither the patient nor the clinician can communicate optimally. Ideally, anesthesia should be decided as part of a birth plan, and this should be discussed and written well before the pregnancy is at term.

Figure 174-1 A, lowa trumpet and syringe with finger rings separated. B, lowa trumpet and syringe with finger rings together.

### **TECHNIQUE**

Because a fairly large volume of anesthetic agent is given, appropriate monitoring of the patient (and, in obstetric cases, the fetus) should be considered. See the Complications section, or Chapter 5, Local and Topical Anesthetic Complications, for symptoms of adverse reactions.

- 1. Timing is important for pudendal anesthesia. Approximately 5 to 10 minutes must be allowed for the anesthetic to infiltrate the nerve and cause its effect. However, for obstetric indications, the anesthetic should be administered neither so early that it blocks effective reflex pushing, nor so late that it wears off before delivery. In nulliparous women, it is usually administered after the cervix has completely dilated and the head has descended to a +2 to +3 station. In multiparous women, the pudendal block may be administered earlier when rapid delivery is expected but should be avoided before the cervix has dilated to 5 cm because it may slow or arrest labor. The resultant anesthetic effect may last for 20 to 60 minutes.
- 2. Place the patient in the dorsal lithotomy position; usually no vaginal preparation is done. In obstetric procedures, (a) the length of time the patient is flat should be minimized, and (b) the fetus must be carefully monitored throughout the procedure and after anesthesia. Universal blood and body fluid precautions should be observed during any obstetric or anesthetic procedure.
- 3. Grasp the Iowa trumpet or needle guide with your sterile-gloved, nondominant hand. The wrist should be pronated, with the thumb through the ring and the shaft between the index and middle fingers. Adequately lubricate the index and middle fingers and use them to protect the vaginal mucosa (and, in obstetric cases, the fetal head). Insert the fingers into the vagina and direct the tip of the guide to the patient's ipsilateral ischial spine (i.e., the left hand of the right-handed operator is used to direct the guide to the patient's left ischial spine). Maintain the guide at an angle nearly parallel to the patient's back (Fig. 174-2).
- 4. Carefully define the anatomy to increase the likelihood of a successful procedure. Attempt to delineate the ischial spine. Slightly below the spine, on its inferoposterior surface, the sacrospinous ligament is attached. Next, attempt to palpate the pudendal artery laterally. Locating these landmarks helps prevent injection of the anesthetic directly into the vessels. It also helps to define the location of the nerve, which is medial to the vessels. If the anatomy is particularly difficult to define, injection just below the ischial spine should be sufficient (but only after aspirating to be certain the needle is not in a vessel).
- 5. With your nondominant hand grasping the syringe, use your dominant hand to direct the needle through the guide, and insert it to the appropriate depth at the desired injection site(s).

**NOTE:** Aspirate for blood with the syringe before injecting anesthetic each time the needle placement is changed. If blood is aspirated, intravascular injection is likely; withdraw the needle and redirect medially, away from the vessels.

6. Inject the desired sites. Usually two to three sites are injected on each side in a fanlike fashion, with a total of 10 mL of local anesthetic injected per side. For the sacrospinous ligament (below/inferior/posterior to spine), some clinicians raise a mucosal wheal at this site with 1 mL of anesthetic and then insert the needle through the wheal until it contacts the ligament. After infiltrating the ligament with 2 to 4 mL of anesthetic, the needle is advanced through the ligament. The clinician will know that the ligament has been traversed when resistance to the plunger decreases. Another 2 to 4 mL of anesthetic can then be easily injected into the loose areolar tissue behind the ligament; another 2 to 4 mL can be injected above/superior/anterior to the ischial spine; and another 2 to 4 mL can be injected medial to the tip of the spine.

NOTE: At each site (except when raising the mucosal wheal below the ischial spine), the needle should be inserted at least 10 mm but not more than 15 mm beyond the needle guide. Each time the needle is redirected, the tip should be drawn back into the guide, the guide redirected, and then the needle advanced to the desired depth.

- 7. Withdraw the needle, refill the syringe, and inject into the opposite side if bilateral anesthesia is desired. Most clinicians prefer to use the same hand for the guide; however, some claim switching hands for the opposite side is more effective. If switching hands, make sure the needle tip is withdrawn to protect yourself from a puncture wound.
- 8. After 5 minutes, check anesthesia on *each* side. Using an Allis forceps, gently scratch over the perineum and watch for the anal "wink" reflex. If there is no reflex to mild stimulus, confirm that the anesthesia is complete with a pinch on each side.
- 9. A smaller repeat dose on a side not demonstrating adequate anesthesia may be used, but care must be taken to avoid doses at which, even with slow absorption from the tissues, toxic serum levels could be reached. Local anesthesia may be used on the perineum to augment the effect, if necessary (when the pudendal block is not completely effective or if it has not had time to take full effect). For example, in the pregnant patient, if the head is descending rapidly, local anesthetic can also be infiltrated into the area where an episiotomy will be made. After the head has been delivered, the pudendal block should have had time to take effect and will usually provide anesthesia for the episiotomy repair.
- 10. As discussed earlier, a pudendal block usually does not provide anesthesia for the upper vagina or cervix. This is important to

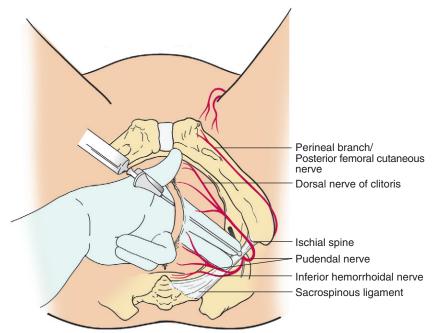

Figure 174-2 Practitioner's left hand is directing guide and needle toward the patient's left pudendal nerve.

remember after delivery when attempting to visualize the entire cervix and upper vagina. If manual exploration of the uterus is necessary, the addition of an intravenous narcotic analgesic may be helpful and appreciated.

# **COMPLICATIONS**

- Systemic anesthetic toxicity is rare and usually results from intravascular administration or an inappropriately high dose. Toxicity may initially cause palpitations, tinnitus, dysarthria, or drowsiness. It may progress to confusion, loss of consciousness, convulsions, hypotension, and bradycardia. Although complications are usually transient, support of the patient's oxygenation and blood pressure is essential (especially to minimize fetal complications in obstetric cases). See Chapter 5, Local and Topical Anesthetic Complications, for management of complications.
- The most frequent complication with pudendal anesthesia is failure to provide adequate anesthesia. Local or regional (e.g., saddle block or epidural) anesthesia should be offered if available.
- Hematomas and infections have been reported but are rare. Infection may spread into the hip joint, the gluteal musculature, or the retropsoas space. Infections may be life-threatening and must be suspected when there is severe pain in the pelvis, back, or hip, limitation of motion, and increasing fever.
- Despite the fact that the anesthetic reaches the neonatal bloodstream after regional anesthesia, studies have failed to demonstrate neonatal neurobehavioral effects or other adverse effects.

# POSTPROCEDURE MANAGEMENT AND PATIENT EDUCATION

There is little need for specific postanesthesia instruction. Remind the patient of the rare but possible complications so that she will report to her clinician if any symptoms develop, especially pelvic, back, or hip pain, limited range of motion, or fever.

### **CPT/BILLING CODE**

64430 Injection, anesthetic agent, pudendal nerve

# **ICD-9-CM DIAGNOSTIC CODES**

650 Normal delivery

The fifth digit (X) is required for codes 651–659 and 660–669 to denote the following:

- 0 Unspecified
- 1 Delivered, with or without mention of antepartum condition
- 2 Delivered, with mention of postpartum complication
- 3 Antepartum condition or complication
- 4 Postpartum condition or complication

Codes related to deliveries with forceps or vacuum

659.7X Abnormality in fetal heart rate or rhythm

662.2X Prolonged second stage of labor

# SADDLE BLOCK ANESTHESIA

Peter W. Grigg

Saddle block anesthesia provides pain relief in the area of the perineum, buttocks, and inner thigh by using an intrathecal (spinal) injection of local anesthetic. A saddle block may be confused with a caudal block (injection of local anesthetic into the sacral canal through the sacral hiatus) because the resultant anesthesia may be similar, but the technique is different. This chapter describes the low-spinal saddle block technique. An ideal "saddle block" anesthetizes the area that would touch a saddle if the patient were riding a horse.

With the advent of more complex techniques for producing analgesia and anesthesia, including single-dose intrathecal opiates and combined spinal epidural and continuous spinal infusions, traditional saddle block (low spinal) is used less often.

Saddle block anesthesia has been used for many years for both surgical procedures and obstetric deliveries. Past problems with profound motor paralysis can be avoided by using lower doses of bupivacaine (e.g., 1 to 2 mL 0.25% bupivacaine [Sensorcaine-MPF] with or without a narcotic). Therefore, variations of saddle block anesthesia can be used midlabor or near delivery.

Clinicians administering saddle block anesthesia must have a good understanding of the anatomy, needle placement techniques, pharmacology, and physiology involved, particularly with regard to the obstetric patient. They must be familiar and experienced with the diagnosis and management of possible complications. A review of the updated American Society of Anesthesiologists (ASA) Guidelines for Obstetric Anesthesia (2006) and the ASA Difficult Airway Algorithms is highly recommended for medical professionals anesthetizing obstetric patients.

Saddle blocks should be performed only in hospitals, surgical centers, or facilities where drugs, equipment, and adequately trained personnel are available to manage any and all possible complications. The equipment available should be comparable with that of the main operating rooms.

### **INDICATIONS**

- For use in obstetrics when time or other circumstances do not allow the use of continuous catheter spinal or epidural anesthetic techniques (e.g., routine delivery, assisted delivery [forceps, vacuum], episiotomy or perineal repair, or other obstetric procedures).
- To provide quick relief so that a laboring patient can remain stationary for epidural catheter placement.
- Genital surgery (e.g., dilation and curettage, hysteroscopy, vaginal surgery, adult circumcision, orchiectomy, or complicated vasectomy).
- Anorectal surgery (e.g., hemorrhoidectomy, fistulectomy, or rectal-anal biopsy).
- As part of a combined spinal epidural technique, when the spinal needle is placed through an epidural needle that is in the epidural space.

### **CONTRAINDICATIONS**

#### **Absolute**

- Patient declines.
- Lack of proper resuscitative equipment, skills, or trained staff.
- Allergy to specific local anesthetics.
- Active systemic infection.
- Moderate to severe hypovolemia.
- Blood dyscrasias; coagulopathy; prolonged international normalized ratio, prothrombin time, or activated partial thromboplastin time; thrombocytopenia.
- Anticoagulant therapy (e.g., heparin, warfarin, enoxaparin [Lovenox], clopidogrel [Plavix]).

### Relative

- Cutaneous lesions of the lower back.
- Spinal abnormalities, including scoliosis and other structural abnormalities.
- Preexisting neurologic diseases (amyotrophic lateral sclerosis, other degenerative nerve diseases, poliomyelitis).
- Preoperative headache.

### **EOUIPMENT AND SUPPLIES**

- Disposable sterile gloves
- Equipment for the clinician to observe universal blood and body fluid precautions
- Disposable spinal tray containing the following
  - Appropriate prep solutions, swabs, and sterile 4 × 4 gauze pads
  - Disposable drapes
  - Syringes
    - 3-mL plastic Luer-Lok for local infiltration of lidocaine 1%
      5-mL procedural syringe for administration of intrathecal agent
  - Needles
    - 3½-inch, 25-gauge spinal needle (pencil point instead of cutting bevel)
    - 20-gauge introducer needle
    - 19-gauge filter needle for drawing solutions into the syringes 25- or 27-gauge skin wheal needle
  - Medications
    - Lidocaine 1% (available in 5-mL vial) for local infiltration Hyperbaric anesthetic
      - Lidocaine 5% (preservative free) in 7.5% dextrose for intrathecal administration (2-mL vial), *or*
      - Tetracaine 1% (2-mL vial) mixed at the time of use with an equal volume of dextrose 10% (5-mL vial) to make the solution hyperbaric, or
      - Bupivacaine 0.75% in 8.25% dextrose (2-mL vial)

Bupivacaine 0.25% methyl paraben free (MPF; for epidural use) plain

Epinephrine 1:1000 (1-mL vial); addition of 0.2 to 0.3 mg (0.2 to 0.3 mL of 1:1000) epinephrine to tetracaine will produce vasoconstriction and prolong the duration of anesthesia by about 50%

Ephedrine 5% (1-mL) in case hypotension develops (the usual dose to treat hypotension is 10 mg [0.2 mL] intravenously [IV])

Fentanyl 50 µg/mL for injection

NOTE: A 1% solution equals 10 mg/mL.

- IV fluids (Ringer's lactate, normal saline)
- Continuous fetal monitoring equipment if used for labor and delivery
- Patient monitoring equipment, including automated blood pressure (BP) device, continuous electrocardiograph (ECG), and pulse oximeter
- Emergency and resuscitative equipment, including suction, positive-pressure breathing device (Ambu-Bag), oxygen, and defibrillator (Having general anesthesia equipment available may be useful [e.g., endotracheal tubes, laryngoscope].)
- Emergency and other drugs not included in the spinal kit
  - Atropine
  - Diphenhydramine (Benadryl)
  - Ephedrine (not included in all commercial spinal kits)
  - Lidocaine for IV injection
  - Metoclopramide (Reglan)
  - Neo-Synephrine
  - Epinephrine
  - Phenylephrine
  - Succinylcholine
  - Propofol, thiopental, and midazolam

### **Anesthetic Agents and Doses**

For saddle block, the three commonly used local anesthetics are lidocaine, tetracaine, and bupivacaine. Lidocaine produces a more rapid onset of anesthesia than tetracaine or bupivacaine; however, it is the shortest acting of the three. Lidocaine generally produces adequate surgical analgesia for 45 to 90 minutes, whereas tetracaine and bupivacaine will last 1½ to 3 hours.

Recently, reports of neurologic sequelae (transient radicular irritation) have raised concerns about the use of lidocaine for intrathecal anesthesia. The risk appears to be reduced if the lidocaine solution is diluted before injection with an equal volume of cerebrospinal fluid (CSF). Tetracaine and bupivacaine are excellent alternatives to lidocaine; however, their increased duration of action requires a longer recovery period.

**NOTE:** For a rapidly progressing obstetric patient, lidocaine may be the only option that will work quickly enough.

Hyperbaric solutions (solutions more dense than CSF) are used for saddle block anesthesia so that in the sitting position the anesthetic solution travels caudad, affecting only the lower levels of the spinal cord. It is important to remember that during pregnancy, inferior vena cava compression will cause engorgement and distention of the vertebral venous system. As a result, there is a decrease in the CSF capacity of the subarachnoid space; therefore, the dose requirements are generally reduced in the pregnant patient.

Near delivery, the usual dose of lidocaine for a saddle block is 25 to 50 mg of 5% lidocaine in 7.5% dextrose (0.5 to 1.0 mL). It should be mixed with equal amounts of CSF before injecting. The equivalent dose of 1% tetracaine is 4 to 6 mg (0.4 to 0.6 mL) plus an equal volume of 10% dextrose solution. For bupivacaine, 5 to 6 mg (0.66 to 0.8 mL of the 0.75% bupivacaine in 8.25% dextrose) should be used. Epidural bupivacaine 0.25% MPF 1 mL (2.5 mg) with 25  $\mu$ g

fentanyl provides less motor block. In surgical procedures for the nonpregnant patient, the doses should be increased.

Confining the anesthetic to a saddle block distribution depends on the dosage and the time that the patient remains in the sitting position after administration of the anesthetic. Too little time in the sitting position (lying down too soon) may produce a higher level of anesthesia than desired, placing the patient at higher risk of hypotension and a higher level of block.

**NOTE:** From an anesthetic perspective, the *level* of anesthesia refers to an anatomic level or segment of effect (e.g., up to the level of the umbilicus [T10], the lower border of the ribs [T8], or the level of the xiphoid [T6]), whereas *depth* refers to the amount of remaining sensation. With saddle block, both motor and sensation are blocked; however, the level of the sensory block is usually two segments above the motor block.

### **PRECAUTIONS**

In addition to a physical examination, a focused history (general maternal health, anesthetic history, allergies, relevant obstetric history, current medications, and NPO status) should be performed with special attention to the airway, vital signs, heart, lungs, and back. Look for contraindications to performing the block.

Expert witnesses in medical liability cases often note a lack of preblock examinations by the anesthesiologist. Laboratory studies are obtained on an individualized basis. Patients should be informed of the risks, benefits, and alternatives to analgesia and anesthesia.

# PREPROCEDURE PATIENT EDUCATION AND FORMS

A fact sheet should be given to the patient to read preoperatively or before the onset of labor (see patient education form available online at www.expertconsult.com). Preferably, the fact sheet should be given to the patient as part of her preoperative assessment or as part of her prenatal care. Shortly before labor, before surgery, or during early labor, the clinician should review the options again with the patient and obtain a signed informed consent (if not done previously).

Desired anesthesia or analgesia should be included in the patient's birth plan. Early and ongoing contact between the obstetrician and anesthesiologist is vital, particularly when significant anesthetic and obstetric risk factors are elucidated.

# **TECHNIQUE**

- 1. Consider giving nonparticulate antacids (Bicitra 30 mL), histamine type 2 blocker (e.g., ranitidine 150 mg), and metoclopramide (Reglan 10 mg) 30 minutes before the saddle block, especially before a cesarean delivery or postpartum tubal ligation. Some clinicians withhold Bicitra because they believe it causes vomiting. ASA Guidelines for Obstetric Anesthesia (2006) permit clear liquids up to 2 hours before saddle block, even in uncomplicated patients undergoing an elective cesarean section.
- 2. Confirm that informed consent and permission forms are signed and in order.
- Establish IV access with a 20-gauge or larger catheter and give a bolus of 500 to 1000 mL of IV fluids. The patient should be well hydrated before the procedure to minimize the risk of developing hypotension.

**NOTE:** Administer IV fluids slowly in women with pregnancy-induced hypertension.

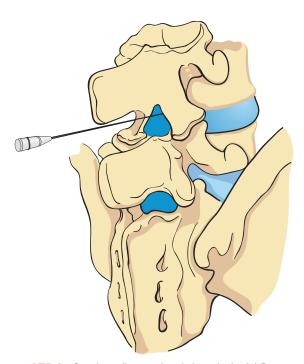

4. For patients in labor, fetal monitoring should be used. For all patients, secure the continuous BP, ECG, and pulse oximetry

monitors and record the initial values. Thereafter, monitor carefully for hypotension by cycling the BP monitor to take measurements at least every 2.5 minutes. Vital signs should be recorded on the anesthesia chart at least every 5 minutes.

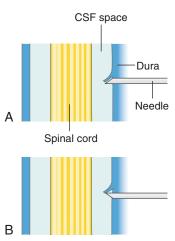

- Open the disposable spinal kit and mix the appropriate solutions. Use the filtered needle to draw up any solutions that will be administered intrathecally.
- 6. Place the patient in the sitting position with the back and neck flexed and the spine straight and not rotated. An assistant should stand in front of the patient during the procedure, helping the patient to maintain the proper position.
- 7. Locate the L2-3, L3-4, or L4-5 interspace. Perform the sterile preparations and drape the area.
- 8. Administer the local anesthesia (lidocaine 1%) to the interspace area by first making a skin wheal, then injecting into the deeper tissues in the same direction that the spinal needle will be advanced.
- Insert the introducer needle into the supraspinous ligament at the proper angle to later direct the spinal needle into the subdural space.

NOTE: The proper angle depends on which interspace is used. At the L4-5 interspace, the proper direction for the needle tip is basically perpendicular (90 degrees) to slightly cranial, whereas it decreases to about 70 degrees (and aimed cranial) at the L2-3 interspace. The proper location is usually just below the inferior edge of the spinous process or slightly below that level (Fig. 175-1). For saddle block anesthesia, insertion angle and location are identical to those used for epidural anesthesia; however, the depth of insertion is unique to each procedure.

10. Insert the 3½-inch, 25-gauge spinal needle into the introducer. Next, advance the spinal needle into the intrathecal space. A "pop" is usually felt when the needle passes through the ligamentum flavum and into the space. Confirmation is obtained when CSF flows from the hub of the spinal needle and continues to do so after the needle is rotated 360 degrees. Rotating

**Figure 175-1** Spinal needle introduced through the L4-5 interspace. Note that the needle is introduced just below the inferior border of the L4 spinous process. The tip is directed at 90 degrees to the spine or slightly cranial.

**Figure 175-2 A,** Bevel of spinal needle occluded by a dural flap after puncture. The flap prevents free flow of cerebrospinal fluid (CSF) through the spinal needle. **B,** Rotating the needle 180 degrees separates the dural flap from the bevel, allowing free flow of CSF through the needle.

the needle ensures that there is no tissue right at the tip of the needle that could later cause an obstruction and prevent injection (Fig. 175-2).

- 11. With the anesthetic solution syringe connected to the hub of the spinal needle, aspirate a small amount of CSF to confirm the placement of the needle. Next, if using lidocaine, withdraw an amount of CSF (0.5 to 1 mL) equal to the amount of lidocaine already in the syringe. Reinject the lidocaine/CSF mixed solution through the spinal needle, slowly, over a period of 5 to 10 seconds. Tetracaine or bupivacaine should also be injected slowly. Do not aspirate or inject during a uterine contraction.
- 12. Remove the spinal needle, syringe, and introducer as a unit. Have the patient remain in the sitting position for 2 to 5 minutes to allow the anesthetic to "set" while it drifts downward into the spinal canal. Allowing the patient to become recumbent or lie in the lithotomy position too soon can result in a higher level of anesthesia than desired. However, if the patient becomes hypotensive, he or she should be returned to the recumbent position immediately and treatment initiated. Otherwise, at the end of the sitting period, place the patient in the lithotomy position. For pregnant women, left uterine displacement should be performed by lifting the uterus slightly and manually pushing or pulling it toward the patient's left side. An assistant should perform this maneuver. This may be facilitated by having the patient turn slightly toward her left side. Left uterine displacement helps minimize or avoid vena caval compression syndrome (decreased venous return to the heart combined with venous congestion around the spinal cord). In a late-trimester pregnancy, this syndrome can lead to prolonged hypotension.
- Check sensation to sharp objects (e.g., a needle) and record the level of anesthesia on the anesthesia record. Once adequate anesthesia has been established, the patient is prepared for delivery.

**NOTE:** The factors affecting the level of anesthesia include (1) the lumbar puncture site, (2) the volume of solution used, (3) the rate of injection, (4) the specific gravity of the solution used, and (5) the position of the patient.

# **COMPLICATIONS**

Intraoperative and postoperative complications of saddle block anesthesia are essentially the same as for higher levels of spinal anesthesia.

# **Intraoperative Complications**

- Hypotension may occur at any time, particularly during and shortly after administration of the anesthetic. It must be corrected rapidly by (1) placing the patient in a recumbent position, (2) infusing a rapid bolus of IV fluids (500 mL), (3) rapidly administering ephedrine 10 mg (IV), and (4) relieving pressure on the vena cava from the pregnant uterus by left uterine displacement. If bradycardia and hypotension occur (from block of cardiac accelerator nerves) give epinephrine quickly. If hypotension and maternal tachycardia are present, then phenylephrine in a 0.1- to 0.5-mg IV bolus dose is acceptable.
- High spinal block with respiratory insufficiency or total spinal block with total respiratory arrest must be treated immediately with respiratory assistance and continued as needed for the duration of the block. Hypotension commonly occurs concurrently.
- Nausea and vomiting may occur concurrently with a drop in blood pressure and usually are relieved with correction of the hypotension by ephedrine (10 mg IV). If accompanied by bradycardia, the nausea and vomiting may regress after treatment with atropine (0.4 to 0.6 mg IV). Nausea and vomiting in the absence of other symptoms may be treated with metoclopramide (10 mg IV).
- Allergic reactions: use diphenhydramine 25 to 50 mg IV.
- Systemic reactions, including cardiac arrhythmia/arrest, are rare.
   To treat this, routine advanced cardiac life support protocols should be followed.

# **Postoperative Complications**

- Headache may occur, with an incidence as high as 5%. Most postspinal puncture headaches can be treated conservatively (oral analgesics, fluids, rest), but some require more aggressive treatment, including a blood patch (see Chapter 206, Lumbar Puncture, for instructions on performing a blood patch).
- Urinary retention sometimes occurs, requiring catheterization.
- Neurologic sequelae (rare), including arachnoiditis, meningitis, palsies, and paralysis.

# **PATIENT EDUCATION GUIDES**

See the sample patient education form available online at www. expertconsult.com.

### **CPT/BILLING CODES**

62273 Injection, lumbar epidural, of blood or clot patch

62311 Injection, single (not via indwelling catheter), not including neurolytic substances, with or without contrast, of diagnostic or therapeutic substance(s) (including anesthetic, antispasmodic, opioid, steroid, other solution), epidural or subarachnoid; lumbar, sacral (caudal)

# **ICD-9-CM DIAGNOSTIC CODES**

For other than pregnancy codes, see the appropriate procedure chapter for ICD-9-CM codes.

Normal delivery

V22.2 Pregnant state, NOS

The fifth digit (X) is required for codes 640–648, 651–659, and 660–669 to denote the current episode of care.

- 0 Unspecified
- Delivered, with or without mention of antepartum condition
- 2 Delivered, with mention of postpartum complication
- 3 Antepartum condition or complication
- 4 Postpartum condition or complication
- 644.2X Premature labor with delivery (<37 weeks)
- 652.2X Breech presentation
- 653.5X Unusually large fetus causing disproportion

Codes related to deliveries with forceps or vacuum

- 659.7X Abnormality in fetal heart rate or rhythm or fetal distress
- 662.2X Prolonged second stage of labor

Codes related to episiotomy and episiotomy repair and codes for repair of low vaginal lacerations

- 664.0X First-degree perineal laceration
- 664.1X Second-degree perineal laceration
- 664.2X Third-degree perineal laceration
- 664.3X Fourth-degree perineal laceration
- 664.4X Unspecified perineal laceration

# Transcervical Amnioinfusion

David G. Weismiller

Amnioinfusion is an inexpensive, minimally invasive, proven therapeutic measure used since 1983 to restore or replace amniotic fluid during labor. It is performed by infusing normal saline or lactated Ringer's transcervically through a catheter. There are two common applications: (1) to assist with the management of variable or prolonged (e.g., lasting as long as the contraction) fetal heart rate decelerations; and (2), until recently, to dilute thick meconium fluid. Overall, the procedure appears to pose little risk while offering considerable benefit in properly selected patients. A survey of 186 teaching hospitals in the United States found that 96% use amnioinfusion, and an estimated 3% to 4% of women in labor receive such an infusion.

In theory, artificially increasing the amniotic fluid volume should protect the umbilical cord from compression, thus reducing the number and severity of variable decelerations. If decelerations become severe, persistent, or prolonged, it is possible for the fetus to become distressed and even require emergency operative delivery. A recent meta-analysis of nine randomized trials provides supportive evidence for amnioinfusion for variable decelerations. Another summary of 12 published randomized trials suggests that using amnioinfusion for infants at risk of cord compression (e.g., repetitive variable decelerations, especially in the presence of oligohydramnios or amniotomy) decreases not only the occurrence of variable decelerations but the number of cesarean sections. Interestingly, amnioinfusion is also associated with a reduction in postpartum endometritis for women at risk.

Previous randomized, controlled trials had suggested that the *prophylactic* use of amnioinfusion for oligohydramnios might reduce the incidence of fetal distress and cesarean intervention. However, recent comparison studies found no advantage to prophylactic amnioinfusion as opposed to using amnioinfusion only when fetal heart rate decelerations occur.

Amnioinfusion has been advocated as a technique to reduce the incidence of meconium aspiration and to improve neonatal outcome. Meta-analyses had suggested that amnioinfusion for moderate to thick meconium reduced the frequency of meconium being found below the infant vocal cords, the incidence of meconium aspiration syndrome, and the cesarean delivery rate. However, a large proportion of infants have already aspirated meconium before meconiumstained amniotic fluid is noted and before amnioinfusion can be performed; meconium passage may predate labor. Meconium passage occurs in three distinct situations: (1) as a physiologic or maturational event, (2) as a response to acute hypoxic events, and (3) as a response to chronic intrauterine hypoxia. It has long been known that the risk of meconium aspiration is high in infants of mothers with thick meconium, particularly if associated with an episode of fetal hypoxia. In contrast, thin meconium is not associated with an increased perinatal mortality rate or incidence of meconium aspiration syndrome. Therefore, diluting meconium in the already potentially compromised fetus is postulated to have a positive effect on neonatal outcome.

Based on current literature (e.g., evidence from a well-designed, randomized, multicenter, prospective trial of 1998 women [Fraser

and colleagues, 2005]), routine prophylactic amnioinfusion for the dilution of meconium-stained amniotic fluid is not recommended. For women in labor who have thick meconium staining of the amniotic fluid, amnioinfusion does not reduce the risk of moderate or severe meconium aspiration syndrome, perinatal death, or other major maternal or neonatal disorders. Prophylactic use of amnioinfusion for meconium-stained amniotic fluid should be done only in the setting of additional clinical trials. Data are not available to determine whether amnioinfusion for fetal heart rate decelerations in the presence of meconium-stained amniotic fluid decreases meconium aspiration syndrome or other meconium-related morbidities.

Different protocols for amnioinfusion are used. However, they all appear to be safe, easy to perform, and associated with few complications.

### **INDICATION**

Repeated severe or prolonged (e.g., lasting longer than the contraction) variable fetal heart rate decelerations that are unresponsive to conventional therapy (e.g., left-sided labor, intravenous hydration, oxygen therapy), regardless of amniotic fluid meconium status, are the indication for amnioinfusion.

**EDITOR'S NOTE:** Obviously, amnioinfusion might be a consideration during labor in *many* pregnancies because variable decelerations are very common. In reality, experienced clinicians use amnioinfusion in certain selected situations. An example is the multiparous patient who has only an hour or so remaining before the second stage of labor, yet the fetal strip shows very deep, severe variables that last a long time (perhaps as long as the contraction). We have all nervously watched such a labor fearing that these deep variables may exhaust the fetus. It is reassuring to have amnioinfusion available as a possible preventive measure. A similar situation may be seen with oligohydramnios, or even borderline oligohydramnios. Often these infants endure a stormy labor with deep variables early in labor. Amnioinfusion may be an option in these situations.

# CONTRAINDICATIONS

- Amnionitis
- Polyhydramnios
- Uterine hypertonus
- Multiple gestation
- Known fetal anomaly
- Known uterine anomaly
- Severe fetal distress
- Nonvertex presentation
- Fetal scalp pH <7.20
- Placental abruption or placenta previa (known or suspected)
- Patient refusal or uncooperative patient

### **EQUIPMENT**

- Intrauterine pressure catheter (see Chapter 171, Intrauterine Pressure Catheter Insertion)
- Normal saline or lactated Ringer's at room temperature
- Fetal monitor
- Intravenous tubing
- Intravenous pump
- Fetal scalp electrode\*
- Sterile gloves (for insertion)
- Vaginal lubricant (for insertion)
- Fluid warmer (if the fluid is to be infused at a rate >15 mL/min)

### PREPROCEDURE PATIENT PREPARATION

Before performing the procedure, discuss it with the patient (and family, if present). Inform her of the risks and explain why amnioinfusion should be beneficial. (For severe repetitive or prolonged variable decelerations, amnioinfusion decreases the number of variable decelerations and cesarean sections and possibly the risk of postpartum endometritis.) Describe alternative modes of intervention (if applicable) and obtain informed consent. Answer any questions that the patient (or family) may have.

# **TECHNIQUE**

- Perform a sterile vaginal examination to confirm cephalic presentation and that the membranes are ruptured (see Chapter 164, Amniotomy), determine the degree of dilation, and exclude a cord prolapse.
- 2. Place a fetal scalp electrode (recommended, not required; see Chapter 168, Fetal Scalp Electrode Application) or ensure adequate fetal monitoring.
- 3. Insert an intrauterine pressure catheter (see Chapter 171, Intrauterine Pressure Catheter Insertion) and document the resting tone. The resting tone should be less than 15 mm Hg.
- Link room-temperature normal saline (or lactated Ringer's) to the intravenous tubing. Prime the tubing as would be done for intravenous use.
- 5. Attach the tubing to the infusion port of the intrauterine pressure catheter (Fig. 176-1).
- 6. For patients with repetitive severe or prolonged variable decelerations
  - Start the infusion with an initial bolus of 250 to 500 mL of fluid over 20 to 30 minutes.
  - Next, adjust the rate of infusion according to the severity of decelerations. The usual infusion rate is 10 to 20 mL/min up to a total of 600 to 800 mL infused or until resolution of the variable decelerations, if that occurs first. (Other experts start with a bolus of 500 mL of room-temperature fluid followed by a continuous infusion of 3 mL/min.)
  - With resolution, continue the infusion for an additional 250 mL beyond the volume at which the decelerations resolved.
  - Terminate the infusion if 800 to 1000 mL of saline does not resolve the decelerations. However, if decelerations do not resolve completely, yet there is an increase in frequency and severity when the fluid is discontinued, it may be prudent to resume the infusion.
- 7. Warm the fluid to body temperature if it is administered at a rate greater than  $15\ \text{mL/min}$ .
- Monitor fetal heart rate and resting uterine tone continuously during the intervention; monitor intrauterine pressure using the same intrauterine pressure catheter, a second one, or a doublelumen catheter.

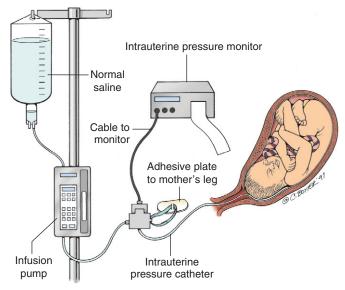

Figure 176-1 Procedure for amnioinfusion. (From Weismiller DG: Transcervical amnioinfusion. Am Fam Physician 57:504–510, 1998.)

- 9. Discontinue the infusion if uterine tone becomes persistently elevated or if the flow of fluid from the vagina stops. Allow the uterine pressure to equilibrate over 5 minutes and reassess the resting uterine tone. Discontinue the infusion if the new resting tone is 15 mm Hg above the baseline resting tone or 30 mm Hg maximum.
- After the initial bolus, it is extremely important to verify that fluid is flowing from the vagina and that volume overload is not occurring.

### **COMPLICATIONS**

There are occasional amnioinfusion failures. The possible causes for failure include inadequate infusion volume or rate, rapid progression to second stage of labor, or cord complications; however, the cause of the majority of failures is unknown.

In another teaching hospital survey intended to determine how, when, and with what results amnioinfusion is being performed in the United States, it was found that neither the method used nor the number of infusions performed appears to significantly increase the risk for complications. The fact that the mean number of amnioinfusions performed per year is similar between centers that did and centers that did not report complications suggests that complications are generally infrequent or, perhaps, that the risk of complication decreases as clinician experience increases. (It also might indicate a reporting problem!)

- Isolated cases of umbilical cord prolapse have been reported, but they are well within the usual occurrence rate of prolapse in pregnancies with vertex presentation, even when amnioinfusion is not used.
- Uterine tone may increase and hypertonus has been reported; thus monitoring intrauterine pressure, the total volume infused, and the continuous flow of fluid from the vagina is important. In one study, this was the most common complication.
- Abnormal fetal heart rate tracings were the second most common complication in one study.
- Prolonged fetal bradycardia has been reported after rapid administration (50 mL/min) of unwarmed fluid.
- Prophylactic amnioinfusion (although not recommended) was associated with increased intrapartum fever.

<sup>\*</sup>Recommended, not required.

- Other reported rare complications
  - Uterine scar disruption (one reported case)
  - Iatrogenic polyhydramnios and elevated intrauterine pressure resulting in fetal bradycardia (one reported case)
  - Amniotic fluid embolism (five reported cases, all associated with previously reported risk factors for amniotic fluid embolism)
- Rare complications associated with placement of an intrauterine pressure catheter
  - Uterine perforation
  - Umbilical cord trauma
  - Placental abruption
  - Fetal trauma
- Amnionitis is a possible complication. Prolonged use of an intrauterine pressure catheter is also associated with an increased risk of amnionitis and perinatal infection.

**NOTE:** Most trials reviewed have been too small to address the possibility of rare but serious adverse maternal effects of amnioinfusion.

# VAGINAL DELIVERY

Dale A. Patterson • Coral D. Matus • Jacob Curtis

Vaginal delivery is a natural process that has gradually become a medical procedure. Although early medical efforts were successful at decreasing the maternal and fetal death rates, more recent and advanced interventions have not been shown to be as successful. Despite routine use in numerous settings, interventions such as electronic fetal monitoring, routine amniotomy, and fetal pulse oximetry have not been shown to improve outcomes. A few medical interventions, including routine episiotomy, have actually been shown to be harmful to the mother or the baby. As in all aspects of modern medicine, new information is available on a regular basis, and it is prudent to stay up to date with this information if attending deliveries.

Even though it is a natural process, labor and delivery is also very complex and varies among patients. Labor can last as little as an hour or less in some patients and take several days in others. The underlying hormonal changes associated with labor are only superficially understood. It is beyond the scope of this text to explore all of the possible variables and complications that could occur during a vaginal delivery. The focus of this chapter is on the uncomplicated vaginal delivery of a single newborn in the vertex position. When available, evidence-based recommendations will be made regarding the delivery technique.

Women in labor frequently undergo procedures related to vaginal delivery. Many of these are described in Section 10, Obstetrics, Chapters 161–177.

# **ANATOMY**

Vaginal delivery begins with the onset of true labor, which is defined by the onset of contractions that are regular, are of increasing intensity, and cause progressive dilation and effacement of the cervix with descent of the fetal presenting part.

Labor is divided into three progressive stages: first stage, from onset of labor until complete cervical dilation; second stage, from complete dilation to delivery of the infant; and third stage, from delivery of the infant to delivery of the placenta.

The average time of each stage is different for nulliparas than for multiparas (Table 177-1). The cervix should dilate 1 cm/hour or more in nulliparas and 1.2 cm/hour or more in multiparas, once active labor begins. Descent should occur at 1 cm/hour or more in nulliparas and at least 2 cm/hour in multiparas. Protraction disorders are defined by a rate of either dilation or descent slower than these minimums.

The first stage of labor may be subdivided into two phases: latent and active. Latent phase labor may occur prior to the onset of the active phase. Latent labor is characterized by mild, irregular uterine contractions that cause softening, effacement, and slow dilation of the cervix. A prolonged latent phase is defined as more than 25 hours for nulliparas and 14 hours for multiparas. Progression at a rate below those defined numbers may warrant intervention, especially in a post-term or prolonged pregnancy (see Chapter 163, Induction of Labor).

As the cervix dilates, the fetus starts its descent through the birth canal. Using the force of each contraction, the fetal head negotiates incrementally through the angles of the maternal pelvis, following a standard pattern known as the cardinal movements of labor:

### 1. Engagement

- Defined by descent of the biparietal diameter of the fetus to a level below the maternal pelvic inlet. The borders of the pelvic inlet are formed by the sacral promontory posteriorly and the inner pubic arch anteriorly; this diameter is also referred to as the "obstetric conjugate." In most cases, the anteroposterior diameter of the pelvic inlet is the smallest dimension. Thus, the smallest diameter of the fetal head (biparietal diameter) must align with the anteroposterior diameter of the pelvic inlet.
- Suggested clinically when the lowest portion of the occiput (not caput) is palpated at or below the maternal ischial spines (0 station).
- In most cases, it indicates the maternal pelvic inlet is sufficient to allow descent of the head.
- Often occurs before the onset of labor, especially in nulliparas.
- Verification may be difficult if the fetal head is molded or in the occipitoposterior (OP) presentation.

# 2. Descent (Fig. 177-1)

- Slow, progressive process.
- Measured by station (level of presenting part) and quantified by number of centimeters the presenting part is above (e.g., -2, -1) or below (e.g., +1, +2) the ischial spines.

# 3. Flexion

 The force of contractions against the cervix and maternal tissue eventually pushes the head into a flexed position so that the smallest diameter of the fetal head presents primarily, further aiding in descent of the presenting part (Fig. 177-2A).
 It remains in this position until the head has descended to the level of the vulva.

# TABLE 177-1 Average Lengths and Upper Limits of Normal for Stages of Labor in Primiparous and Multiparous Women

	Lengths		
Stage of Labor	Primiparous Women	Multiparous Women	
First (latent phase) First (active phase) Second Third	5.9 to 6.4 (25.1*) hrs 3.3 to 7.7 (17.5*) hrs 33 to 54 (146*) mins 5 (30*) mins	4.8 (13.6*) hrs 3 to 7 (13.8*) hrs 8.5 to 18 (64*) mins 5 (30*) mins	

\*Upper limit of normal.

From Patterson DA, Winslow M, Matus CD: Spontaneous vaginal delivery. Am Fam Physician 78:336–341, 343–344, 2008.

**Figure 177-1** Descent of fetal head into the pelvis. Zero station is diagnosed when the fetal vertex has reached the level of the ischial spines. (Redrawn from Niswander K: Obstetrics: Essentials of Clinical Practice, 2nd ed. Boston, Little, Brown, 1981.)

- Normally, the posterior fontanelle is in the center of the dilating cervix, allowing for optimal "molding" of the fetal cranial bones and sutures.
- Infants in an OP position often assume a more "deflexed" position due to their orientation in the maternal pelvis. This causes a less favorable alignment between the fetal head (passenger) and the maternal pelvis (passageway).

### 4. Internal rotation

As the fetal head continues to descend, the biparietal diameter of the fetus rotates to align with the lateral diameter (intertuberous diameter, or the distance between the ischial tuberosities) of the maternal pelvic outlet. Typically this intertuberous diameter constitutes the smallest dimension of the

- pelvic outlet. The borders of the pelvic outlet are formed by the ischial tuberosities laterally, and the angle of the pubic symphysis anteriorly.
- The final position of the vertex is usually left occipitoanterior (LOA) (Fig. 177-2B), occipitoanterior (OA) (Fig. 177-2C), or right occipitoanterior (ROA); however, in about 5 to 10 percent of cases, the vertex presents in an OP position.

#### 5. Extension

- The force of contractions from above meets the force of resistance from the pelvic muscles below and interacts to use the pubic symphysis as a fulcrum. This combination of forces and a fulcrum pushes the head around the pubic bone (Fig. 177-2D).
- The head becomes extended with delivery as a result of these forces.
- Extension occurs fairly rapidly and is observed clinically when the perineum distends.

#### 6. External rotation and restitution

 After delivery, the head rotates back to a transverse position and the shoulders rotate into an anteroposterior (AP) position, before they are delivered (Fig. 177-2E).

Although dilation and descent may occur predictably, more often the pattern of labor is irregular and erratic. The original labor curves plotted by Friedman in the 1950s have since been adjusted to fit a slower average progression of labor as seen in many patients with epidural analgesia (see Table 177-1). Common pitfalls of early labor management include admission to the hospital too early during latent phase labor. Women admitted in latent labor tend to spend more time in the labor unit and have more interventions than those in whom admission is delayed until active labor is confirmed.

In an attempt to reduce prolonged labor in nulliparas, the active management of labor (AML) protocol was created and studied at the National Maternity Hospital in Dublin, Ireland. AML refers to active control, rather than passive observation, by the obstetric provider during the active phase of the first stage of labor. Initially, this protocol demonstrated a shortened labor and a decrease in the cesarean delivery rate. Subsequent studies in the United States did

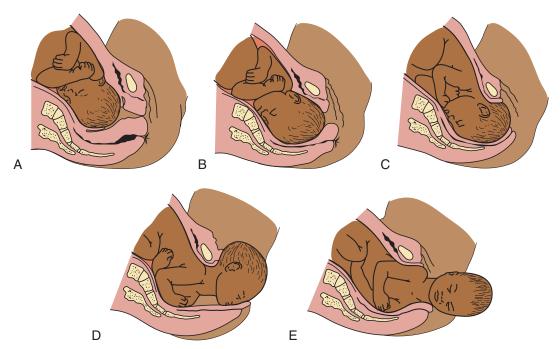

Figure 177-2 A, Engagement of flexed head. B, Left occipitoanterior (LOA) position. C, Internal, anterior rotation of head to occipitoanterior (OA) position. D, Extension of head. E, External rotation of head. (Redrawn from Pernoll M: Benson and Pernoll's Handbook of Obstetrics and Gynecology, 9th ed. New York, McGraw-Hill, 2001.)

not confirm the decrease in cesarean deliveries. This protocol has generated much controversy and there is no clear consensus that it should be universally adopted. However, it may be appropriate for some patients. The AML protocol for nulliparas has four underlying teners.

- 1. Extensive prenatal education
  - Women are educated about the signs of true labor and reasonable expectations during active labor. They are also assured that they will have continuous support during labor. Continuous support by an experienced (parous) laywoman or doula and emotional support early in labor may be more critical than support given to a woman after she is admitted to the hospital and may have already chosen an epidural.
- 2. A specific definition of labor, which includes not only the presence of painful uterine contractions, but also *one* of the following:
  - Presence of bloody show (blood-stained mucus)
  - Complete cervical effacement, regardless of dilation
  - Rupture of the membranes

**NOTE:** The correct diagnosis of labor is considered to be the single most important factor in AML because an incorrect diagnosis may lead to inappropriate or ineffective interventions.

- 3. Close monitoring of labor progress, every 1 hour for the first 3 hours after diagnosis of labor and admission to the labor ward. Subsequently, examinations are performed at no longer than 2-hour intervals. If cervical dilation is not progressing at a rate of at least 1 cm/hour, intervention is indicated.
- 4. Intervention if progress does not proceed as expected
  - Early amniotomy (1 hour after admission, see Chapter 164, Amniotomy) to allow assessment of amniotic fluid was a component of the original AML protocol, although it has not been shown to significantly reduce the duration of labor.
  - High-dose oxytocin (start with 6 mU/min and increase every 15 minutes) was also a component of the original AML protocol. Subsequent studies have questioned the safety of such high-dose protocols, citing complications such as maternal water intoxication and uterine hyperstimulation.

# **INDICATIONS**

- Vertex presentation, active labor, vulva distended, and deliverable baby
- Fetal distress in a deliverable baby

### **CONTRAINDICATIONS**

### **Absolute**

- Cord prolapse
- Complete placenta previa or vasa previa
- Abnormal fetal lie (e.g., footling breech, transverse lie, persistent brow presentation)
- Prior classical cesarean section or transfundal uterine surgery
- Herpes simplex infection with active genital lesions or prodromal symptoms
- Untreated human immunodeficiency virus (HIV) infection

### **Relative**

- Pelvic deformities
- Congenital deformities (hydrocephalus)
- Invasive cervical carcinoma
- Treated HIV infection
- Macrosomia
- Malpresentation (including breech)
- Previous low transverse cesarean deliveries
- Multiple gestation

### **EQUIPMENT AND SUPPLIES**

Although equipment setups vary, depending on the hospital or the staff, the following list is found in a standard *birthing room*. In addition to what is listed, deliveries in an *operating room* require a full gown, a mask, and foot and head covers.

- Oxygen with flowmeter (one setup for mother and another for infant)
- Delivery bed (should be able to break down into a modified lithotomy position and have adjustable height)
- Setups for uterine contraction and fetal monitoring (optional, see Chapter 168, Fetal Scalp Electrode Application)
- Setup for infant (infant warmer, oxygen with bag and mask, suction with DeLee, infant laryngoscope, intubation equipment, umbilical catheter, medications, and monitoring equipment for resuscitation [see Chapter 180, Neonatal Resuscitation])
- Sterile equipment tray or table containing the following (Fig. 177-3)
  - 10-mL tube for cord blood
  - Two pairs of scissors (blunt Mayo-Noble straight scissors for cutting the cord and episiotomy and sharp scissors for cutting suture and dressings)
  - Bulb syringe
  - One plastic cord clamp (may use curved artery Kocher clamp for the other; some clinicians use three plastic cord clamps if cord blood is routinely sent for gases)
  - Two curved artery Kocher clamps (some clinicians like to have four of these clamps, especially if cord blood gases are to be sent)
  - Needle holder
  - Two ring forceps clamps (also called a sponge stick or placenta forceps)
  - Drapes and towels (including under buttocks drape with fluid pouch)
  - Placenta basin
  - Gown (optional) and sterile gloves (latex-free recommended)
- Optional equipment for sterile tray or table (also see Chapter 166, Episiotomy and Repair of the Perineum)
  - Additional pair needle holder
  - Two Allis clamps (for third- or fourth-degree repair)
  - Two thumb tissue forceps (one with teeth and one without teeth)
  - Gelpi retractor (for added visualization during a third- or fourth-degree repair)

**Figure 177-3** Instruments for vaginal delivery. *Left to right:* Cord blood tube, two scissors (blunt and sharp edge), bulb syringe, plastic cord clamp, two curved artery Kocher clamps (one is holding plastic cord clamp), needle holder, two ring forceps (one grasping folded  $4 \times 4$  gauze is called sponge stick).

- Weighted speculum (offers greater visualization of the vaginal wall and cervix)
- 10-mL syringe
- 22-gauge, 1½-inch needle (for local anesthesia)
- 1% lidocaine, without epinephrine
- Two 3-0 absorbable synthetic sutures with tapered needles
- Gauze pads (4 × 4 inch)
- Sterile speculum
- Red rubber, straight, in and out catheter— povidone-iodine, chlorhexidine, or surgical soap or solution for preparation
- Emergency kit (for precipitous deliveries)
  - Sterile gloves (large size)
  - Two sterile towels
  - One pair of blunt-ended scissors
  - One plastic cord clamp
  - Two curved artery Kocher clamps
  - Gauze pads  $(4 \times 4 \text{ inch})$
  - Bulb syringe
  - Placenta basin

### **PRECAUTIONS**

All women with prior history of cesarean delivery for any indication should be cautioned about the options for mode of delivery in subsequent pregnancies and the risks and benefits of each option. Certain patients (those with prior "classical" or "T" type uterine incision) should be cautioned against laboring. Those with a single prior low transverse uterine incision should be allowed to consider a trial of labor with informed consent. It is imperative that these patients understand the risk of uterine rupture with vaginal delivery and the risks of repeat surgical delivery. Selecting women most likely to give birth vaginally (e.g., those with prior vaginal birth or those with indication for prior cesarean delivery other than dystocia) and avoiding the use of prostaglandins or misoprostol offer the lowest risk of complication. Many institutions have strict criteria for allowing women with prior cesarean delivery to attempt a vaginal birth after cesarean delivery (VBAC). It is prudent to ensure that facilities are able to provide immediate repeat cesarean delivery in case of emergency and that close monitoring by trained personnel is available.

Group B streptococcus (GBS) colonization occurs in 10% to 30% of women. The incidence of early onset neonatal infection with GBS, the most common serious infection of the newborn period, can be reduced with intrapartum chemoprophylaxis of women who test positive for GBS. The Centers for Disease Control and Prevention recommends routine screening for GBS in all pregnant women at 35 to 37 weeks' gestation with rectal and vaginal swab. If positive, treatment with penicillin (5 million units) at least 4 hours prior to delivery and repeat doses every 4 hours (2.5 million units) is first-line therapy. If unable to use penicillin, options for GBS prophylaxis during labor include ampicillin, cefazolin, clindamycin, erythromycin, and vancomycin. Other indications for intrapartum prophylaxis are GBS bacteriuria during pregnancy and previous neonatal infection with GBS. Women with these risks should not be screened at 35 to 37 weeks; they should just be treated (regardless of results).

Other maternal conditions that warrant preprocedure evaluation and counseling include maternal cardiovascular conditions, coagulopathies, diabetes, and other chronic medical conditions. Discussion of each of these is beyond the scope of this text, but each patient with potential complications should have an appropriate management plan prior to the onset of labor and a labor and birth plan accounting for the risks formulated.

### PREPROCEDURE PATIENT EDUCATION

One focus of prenatal care is education. In an ideal situation, the patient will have several months to prepare and numerous encounters with her provider prior to a vaginal delivery. The breadth of prenatal education is beyond the scope of this text. There are many

resources available to guide education and many prenatal record keeping products incorporate education into their program. See the resources listed under "Useful Continuing Education" later in this chapter.

In general, a pregnant patient should be educated about the process of pregnancy and behaviors that increase her chances of an uncomplicated delivery with a healthy newborn. Topics that should be addressed in pregnancy include whether to continue exercise and for how long; avoiding tobacco, alcohol, and other drugs; and eating a healthy diet.

The birth process is intimidating for many women, especially first-time mothers. Education about the normal birth process can greatly relieve these fears and improve a women's experience of labor. Some form of a birth plan is helpful for the patient and the provider (Fig. 177-4). Topics to discuss include pain control, the uncertainty of labor, and the possibility of interventions, including episiotomy and cesarean delivery. The patient should be encouraged to ask questions so that her concerns are adequately addressed.

As the rate of operative deliveries in the United States continues to increase, more patients may express a desire for an elective cesarean delivery or a repeat cesarean delivery. The question of whether a patient should be allowed to choose an elective primary cesarean delivery is an ethical debate. Despite advances in anesthesia and surgical care, a vaginal delivery is a safer procedure than a cesarean delivery. Vaginal birth after cesarean delivery can also be a safe procedure in the appropriate setting. See earlier discussion under "Precautions."

Overall, patients should be educated about the normal birth process and the risks and benefits of the multiple options they may encounter during labor. Because vaginal delivery is the safest method of delivery, it should be encouraged. The provider should be aware of local standards of care and communicate these to the patient prior to the onset of labor when they may affect the management of her labor.

# **TECHNIQUE**

# First Stage

Management of the first stage of labor should be passive during the latent phase. Once the active phase has begun, labor should be monitored for progression and intervention considered if adequate progress toward delivery is not achieved. AML can be considered by the patient and maternity care provider. Arrest of labor is defined as no change in dilation with adequate contractions for 2 hours. Adequacy of contractions can be assessed by inserting an intrauterine pressure catheter (IUPC; see Chapter 171, Intrauterine Pressure Catheter Insertion). Although there is no definitive time to mandate cesarean delivery, it should be considered after 2 to 4 hours of oxytocin augmentation of labor without cervical change.

### **Second Stage**

Typically, as the cervix nears complete dilation, the intensity of the contractions increases and the patient starts to feel the urge to push. Even if the patient has regional anesthesia, she will usually feel pressure as the fetus begins to descend more rapidly. When the cervix is completely dilated, the second stage of labor has begun and the patient may begin to push. It is contraindicated to push prior to complete dilation of the cervix as soft tissue injury and maternal exhaustion are likely.

After the second stage of labor has begun, the length of time until delivery varies (see Table 177-1). Two or three explosive pushes may be enough to deliver a multipara, whereas a nullipara with regional anesthesia may push for more than an hour. If labor stalls during this stage, oxytocin augmentation should be considered. To prevent maternal exhaustion, if the infant is stable, alternating periods of rest and pushing is recommended. If the mother is comfortable and the infant appears to be tolerating the labor process, it

Figure 177-4 Sample birthing plan.

is reasonable to delay pushing until the vertex is at the introitus or the mother feels a strong urge to push. If the vertex is at +2 or greater station, forceps or vacuum-assisted delivery may be considered after 1 hour of pushing in a multipara or 2 hours in a primipara (after 2 hours in a multipara or 3 hours in a nullipara if a regional anesthetic is being used; see also Chapter 169, Forceps- and Vacuum-Assisted Deliveries).

One of the most common reasons for a prolonged second stage of labor is persistent OP position. On average, the OP position will prolong labor by 1 hour in multiparas and 2 hours in nulliparas. Consider the possibility of OP position if labor is predominantly felt in the back. A persistent anterior cervical lip or an easily palpable

anterior fontanelle may also be associated with the OP position. To confirm the OP position by examination, the infant's skull sutures should be followed until the posterior fontanelle can be palpated. (Recall that the anterior fontanelle is shaped like a cross or plus (+) and is usually larger than the posterior fontanelle; the posterior fontanelle is shaped like a Y.) If an ear is palpable, the direction that the ear is facing will also help determine which direction the baby is facing.

To rotate the fetus from the OP position, any maternal position that causes her to curl forward from the hips is felt to be helpful. Various positions and activities can be tried, such as squatting or ambulating, or placing mother on her hands and knees, on her

side, or with her back arched. The theory is that with most of these positions, the infant will become uncomfortable and be encouraged to turn itself. If the various positions fail to cause rotation, manual rotation can be attempted. Place the mother in the lithotomy, lateral Sims', or hands and knees position. With a hand in the posterior pelvis behind the occiput, attempt to rotate and flex the head, during a contraction, while the mother is pushing. If the fetus is straight OP, the clinician's dominant hand should be used. If the fetus is partially rotated, use whichever hand is easiest to rotate it in the direction of the shortest distance to OA. (If a vacuum-assisted delivery is to be performed, the vacuum device can sometimes help rotate the infant from OP to OA; see Chapter 169, Forceps- and Vacuum-Assisted Deliveries.)

Preparation for delivery should begin at the onset of the second stage for the multipara and as the vertex reaches the pelvic floor in the nullipara.

### Preparation

- Put on sterile gloves and consider a gown. Remember to observe universal blood and body fluid precautions.
- 2. Prepare the delivery tray.
- 3. Turn on the warmer for the bassinette and notify the nursery staff for meconium-staining or fetal distress. Make sure that all necessary equipment is available for a neonatal resuscitation (see Chapter 180, Neonatal Resuscitation).
- 4. Verify that all needed equipment is on the sterile tray or table and within reaching distance. Empty the mother's bladder (usually requires using a catheter with aseptic technique if she has had an epidural).
- 5. Make an attempt to rotate a persistent OP vertex to an OA position if necessary.
- 6. Wash the perineal area with a surgical soap or solution (*optional*). There is no evidence to support shaving the perineum or enemas at this stage of delivery.

# Position of the Woman

Allow the patient to find a comfortable position for pushing and resting (Fig. 177-5). The rationale for each position is noted here, as well as possible inconveniences or complications for each position:

- 1. Modified dorsal
  - Semisitting position with knees flexed and legs widely separated; the mother can grip below her knees for leverage when pushing
  - Good position for multipara deliveries
- 2. Squatting, kneeling (see Fig. 177-5A)
  - More physiologic for pushing
  - Less discomfort with pushing
  - Fewer perineal tears
  - Increased incidence of hemorrhage
- 3. Lithotomy (see Fig. 177-5B)
  - Better access for the provider, so this position is often used for instrumentation
  - Difficult position for pushing
  - Increased risk for maternal aspiration
- 4. Left lateral (see Fig. 177-5C)
  - · Left side with knees flexed and separated
  - Offers better clinician access for head control
  - Need an assistant to hold upper leg

### Anesthesia (Optional)

- Regional anesthesia (see Chapter 3, Epidural Anesthesia and Analgesia; Chapter 170, Intrathecal Analgesia in Labor; and Chapter 175, Saddle Block Anesthesia)
- Paracervical block, for first stage of labor to decrease the discomfort with contractions (see Chapter 173, Paracervical Block)
- Pudendal block, for perineal pain (see Chapter 174, Pudendal Anesthesia)
- Local infiltration of lidocaine if episiotomy is required (routine episiotomy is contraindicated; see Chapter 166, Episiotomy and Repair of the Perineum)

### **Delivery**

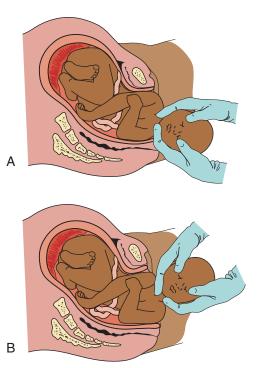

There are many variations in technique for vaginal delivery. There is not one "right" way to deliver a vertex infant. Two commonly debated techniques are the "hands on" and "hands poised" techniques. Essentially, the "hands on" technique is a process by which the provider puts pressure on the baby's head and supports the mother's perineum throughout the delivery process. The "hands poised" technique requires the provider to allow spontaneous

Figure 177-5 Maternal birthing positions. A, Squatting; B, lithotomy; C, left lateral.

delivery of the head prior to any intervention. No significant differences in outcomes have been shown between the two methods and either is acceptable practice. This section will describe the "hands on" technique. The "hands poised" method is similar after delivery of the infant's head.

- Observe the perineum for distention due to the fetal head. When
  the head is visible ("crowning"), it is appropriate to apply pressure to the infant's head to control the force of delivery and
  to support the perineum with gentle pressure. Either hand may
  be used.
- 2. If an episiotomy is to be performed, the best time to perform it is when the opening is 5 to 6 cm (see Chapter 166, Episiotomy and Repair of the Perineum). This procedure is clearly *not* indicated as a routine part of every vaginal delivery. It is usually performed only if it is unsafe for the mother to push (cardiac disease or prolonged second stage), for significant fetal distress (to expedite delivery), before reducing a shoulder dystocia, if an infant is premature or breech, or to make room if there is risk of perineal trauma (e.g., large infant or use of forceps or vacuum). Many episiotomies are appropriately cut at the time an indication presents and may not be performed at this "ideal" time.
- 3. As the head advances, make sure to control its progress. Maintain flexion of the head with pressure applied through a towel placed on the perineum. The head should be delivered slowly, in a controlled manner, as it edges forward with each contraction. Between contractions the head will gradually extend. Recall that as the head extends, it will increase in diameter. Therefore, do not allow the head to extend too rapidly or the chin may tear the perineum. In other words, palpate the chin (through the towel over the perineum), and prevent it from "popping" (suddenly extending) and tearing the perineum.
- 4. If a rapid delivery is necessary (e.g., fetal distress) or assistance is needed (e.g., inadequate pushing because of regional anesthesia or maternal exhaustion), a modified Ritgen maneuver can be used. The Ritgen maneuver merely assists or exacerbates the extension of the fetal head. To perform it, while palpating the infant's chin (through the towel on the perineum), pull outward on the chin and then press it upward to extend the head. Again, this effort should be weighed against the possibility of the chin "popping" through the perineum and tearing it. In most cases, the chin can be controlled and extended enough for delivery without "popping" the perineum.
- 5. For an OP delivery, the head is usually delivered more readily by applying flexion, not extension. The tension on the perineum can be very high, resulting in a third- or fourth-degree laceration. Again, assisting and controlling the amount of flexion with a hand, through the towel on the perineum, may minimize the risk of lacerations.
- 6. As the head is slowly delivered, reach around the neck to check for and reduce a nuchal cord (occurs in 20% of deliveries). Reduction is accomplished by pulling the cord over the delivered head. If the nuchal cord cannot be reduced, it can be doubly clamped and cut at the perineum. (At that point, the infant should be delivered without delay because the infant's blood supply and oxygenation are interrupted until fully delivered.) After the head is delivered, in most cases the mother should be instructed to stop pushing. Wipe the mucus off the infant's nose and mouth while suctioning both orifices with a bulb syringe. The head has now rotated to allow the shoulders to assume an AP position.
- 7. Delivery of the shoulders should be performed with slow and deliberate motions and without exerting excessive traction. Gently depress the head toward the maternal coccyx (Fig. 177-6A), and when the anterior shoulder has passed the symphysis (downward traction becomes much easier and a "pop" may be felt), lift the fetal head upward (Fig. 177-6B). Lifting the head in this way allows for delivery of the posterior shoulder. It is

**Figure 177-6 A,** Gentle downward traction to bring about descent of anterior shoulder. **B,** With delivery of the anterior shoulder completed, applying gentle upward traction delivers the posterior shoulder. (Redrawn from Ratcliffe S, Baxley EG, Byrd J, Sakornbut E: Family Practice Obstetrics, 2nd ed. Philadelphia, Hanley & Belfus, 2001.)

important to protect the perineum again with one hand through a sterile towel. As the posterior shoulder is delivered, it should also be prevented from "popping" through the perineum and tearing a third- or fourth-degree laceration. If shoulder dystocia is a concern, attempt to deliver the head and shoulders in one continuous motion, which may prevent the anterior shoulder from lodging or becoming impacted against the symphysis.

**EDITOR'S NOTE:** Although management of shoulder dystocia is beyond the scope of this chapter (see "Useful Continuing Education" section), one or two of the maneuvers used in that situation, known as the Rubin II or Woods' screw maneuvers, can be used for all large babies (or small pelves), even in the absence of dystocia. It is the editor's opinion that by using such maneuvers with all large babies, it may minimize the number of tears and the amount of local trauma. Having practiced these maneuvers during routine deliveries may also be beneficial when a shoulder dystocia finally occurs. To perform the Rubin II maneuver, enter the vagina with your hand and apply two fingers to the back of the anterior shoulder of the infant. Apply pressure to rotate it toward the front of the infant and in effect "shrug" the baby's shoulders (adduct them). This will decrease their AP diameter. At the same time, the clinician's other hand can be applied to the infant's posterior shoulder from the front of the infant. Applying pressure here will abduct this shoulder, and rotate it toward the back of the infant. With both maneuvers applied at the same time, the infant's shoulders turning together approximates the turning of a threaded screw (Woods' screw).

8. Next, hold the baby's neck and place a finger in the infant's axilla to maintain lateral flexion of the trunk. The trunk is easily delivered with gentle, continuous traction. Support the trunk with the hand not supporting the neck. Many clinicians feel that the infant should be held just below the level of the introitus with the head down to be suctioned. The cord should then be clamped.

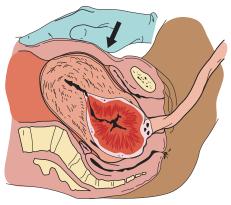

In vitro data support that this is the proper level and time for optimal placental—fetal transfusion. However, no outcome studies support this assertion. In an attempt to increase bonding, some clinicians place the newborn on the mother's chest or abdomen while clamping the cord. The infant should be dried rapidly with towels while assessing it.

# Third Stage

Active management of the third stage of labor has been shown to decrease maternal blood loss, postpartum hemorrhage, length of the third stage, and the need for maternal blood transfusion. Despite an increase in maternal nausea and vomiting, active management of the third stage of labor is highly encouraged.

- Once the anterior shoulder has been delivered, administer an oxytocic agent. Twenty to 40 units of oxytocin added to a liter of intravenous (IV) fluid is a common choice.
- 2. When clamping the cord soon after delivery, the plastic clamp should be placed about 3 to 4 cm from the umbilicus. A curved artery Kocher clamp should then be placed about 3 to 5 cm distally. Cut the cord between the clamps and, as clinically indicated, pass the infant to the mother, nurse, or nursery personnel. (If the collection of cord blood gases is desired, two additional plastic or Kocher clamps should be applied to the cord 10 to 20 cm distal to the curved artery clamp [closer to the introitus]. The cord can be cut again between the most distal clamps and the interval portion of cord sent to the laboratory doubly clamped. Alternatively, the blood for gases can be collected on-site. Samples should be obtained from the umbilical vein, as well as from one of the umbilical arteries, by drawing blood into a 1- or 2-mL syringe flushed with heparin; the samples should be labeled and transported on ice to the laboratory immediately. A delay in clamping or collection can cause inaccurate results.)
- 3. Release the clamp on the cord still attached to the placenta to collect 7 to 10 mL of cord blood while verifying that the cord has two arteries and a vein. Fetal anomalies are associated with cords having fewer than three vessels. After the cord blood is collected, the clamp may be reapplied or left off to allow the placenta to drain. Allowing cord blood to drain will decrease the length of the third stage.
- 4. While waiting to deliver the placenta, place one hand (on a sterile drape) over the fundus and palpate it. Use the other hand to apply firm traction on the cord. Avoid overaggressive traction, however, which may detach the placenta from the cord and cause hemorrhage. Monitor the uterus for atony and uterine inversion (see "Complications" section) by continuous palpation.
- 5. As the uterus becomes more rounded, the cord will usually lengthen, and a gush of vaginal blood indicates placental separation. Usually the placenta separates within 5 minutes of the delivery but it can take as long as 30 minutes. Once the separation occurs, have the mother bear down gently. This is normally enough pressure to expel the placenta. If not, "milk" the placenta out of the birth canal by placing one hand on the fundus and using it to exert a slight to moderate amount of pressure. This should propel the placenta into the vagina (Fig. 177-7). Most clinicians deliver the placenta with gentle twisting traction to help remove membranes. After the placenta has passed through the introitus, gently remove any remaining or attached membranes with a ring forceps. This removal prevents tearing the membranes and decreases the chance of any being left behind.

If the placenta has not delivered within 30 minutes, it may be trapped by a contracted cervical ring. This diagnosis is likely if the uterus has already contracted, the gush of vaginal blood occurred, and the cord lengthened. The Brandt maneuver will often deliver the placenta: apply firm pressure suprapubically to hold the uterus

**Figure 177-7** Expression of placenta. Note that the hand is *not* trying to push the fundus of the uterus through the birth canal! As the placenta leaves the uterus and enters the vagina, the uterus is elevated (fundus pushed upward and posteriorly) by the hand on the abdomen (*arrow*) while the cord is held in position. The mother can aid in the delivery of the placenta by bearing down. As the placenta reaches the perineum, the cord is lifted, which in turn lifts the placenta out of the vagina. Adherent membranes are eased away from thin attachments to prevent their being torn off and retained in the birth canal. (Redrawn from Cunningham FG, Gant NF, Leveno KJ, et al (eds): Williams' Obstetrics, 18th ed. East Norwalk, Conn, Appleton & Lange, 1989.)

in place, apply firm traction on the umbilical cord, and attempt to deliver the placenta.

### Manual Delivery of the Placenta

Manual removal of the placenta is indicated (3% of vaginal deliveries) if the placenta does not deliver within 30 minutes or if significant bleeding occurs and the uterus does not contract. For failure of the uterus to contract, the injection of oxytocin (2 mL/20 IU in 20 mL of normal saline) into the placental side of the clamped cord may be helpful. It will occasionally result in contraction of the uterus and delivery of the placenta.

For manual removal, change gloves and enter the vagina with the dominant hand, palpating for lacerations. Next, find the cervix and enter the uterus. With two or three fingers, and then the whole hand if necessary, find the plane between the placenta and the uterine wall. Gently follow this plane and use the hand to separate the placenta from the uterine wall. After complete separation, hold onto the placenta with the dominant hand, and slowly withdraw the hand with the placenta. If the cleavage plane cannot be separated or parts of the plane cannot be developed completely, prepare for surgical removal of the placenta.

After the third stage, always examine the placenta to see if it is complete while it is in the basin or on the table. If a portion is missing, re-enter the vagina and uterus manually to perform this same maneuver to retrieve any fragments. Covering the sterile glove on the inserted hand with one  $4\times 4$  gauze pad may give additional traction when sweeping the uterus. Such sweeps may also be useful in patients after VBAC, for those bleeding excessively, or for premature deliveries. When the placenta is being examined for completeness, this is another chance to confirm (if you have not already done so) that the cord has three vessels.

If it has not already been given, IV oxytocin should be administered and gentle uterine massage performed to prevent atony. Currently, in the United States, it is the clinician's choice as to whether to give oxytocin with the delivery of the shoulders or after the placenta is expelled. The evidence suggests that giving the oxytocic agent immediately after delivery of the anterior shoulder is beneficial to the patient. Usually this is given intravenously (20 to 40 units in 1 L of isotonic solution over 8 hours). If atony and bleeding persist, intramuscular (IM) methylergonovine (2 mg IM [normotensive patients only]) or 15-methyl prostaglandin (250  $\mu g$  IM) can be given. After the uterus is firm, begin any necessary repair.

### SAMPLE OPERATIVE REPORT

Patient is a 28-year-old female G2P1 at 39 weeks' gestation, admitted for rupture of membranes and contractions. She was 3 cm dilated at admission and progressed to complete without intervention. Fetal heart monitoring remained reassuring throughout labor. Epidural anesthesia was provided. Patient delivered a viable female infant over intact perineum via normal spontaneous vaginal delivery (NSVD) at 08:35. Amniotic fluid was clear. Nuchal cord × 1 easily reduced. Anterior shoulder delivered with gentle traction. Infant was bulb suctioned at perineum. Infant was vigorous, with Apgar scores of 8 and 9 at 1 and 5 minutes. Cord was clamped and cut immediately after delivery and infant was placed on maternal abdomen. Cord blood sent for analysis. Blood gas with pH 7.28. Oxytocin 40 units in 1 L of normal saline started IV at delivery of the anterior shoulder. Placenta delivered intact with three-vessel cord via active management at 08:42. Cervix, vagina, and perineum explored and intact. Estimated blood loss 300 mL. Mother and newborn were stable and remained in the delivery room.

If vacuum or forceps are applied, be sure to include in the delivery note indication, consent, position, station, number of applications, and time of application.

### **COMMON ERRORS**

- Admitting patient to the labor ward prior to the onset of active labor. Being certain of the diagnosis of active labor and delaying admission to the hospital until active labor is confirmed have been shown to decrease the number of interventions a woman undergoes prior to delivery.
- Failure to diagnose breech presentation (or other malpresentation). If not completely certain of the position of the baby after performing Leopold's maneuvers, intrapartum ultrasound confirmation of lie should be considered (see Chapter 172, Obstetric Ultrasonography).
- Failure to recognize nonreassuring fetal tracing. A team approach involving the nurses and delivering providers enhances the ability to detect abnormalities in the fetal heart tracing. As with all skills, continuing education is essential for all caregivers interpreting strips.
- Failure to actively manage the third stage of labor. Good evidence shows that this protocol will decrease postpartum hemorrhage, but it has been slow to be adopted in some settings.
- Performing unnecessary episiotomy. Routine episiotomy should not be performed.
- Poor documentation of labor and delivery. It is essential to document the provider's presence and involvement in the delivery process. As with all care, any intervention needs to be documented in the medical record.

# **COMPLICATIONS**

# **Maternal Complications**

- Perineal pain and dyspareunia are common complications of vaginal delivery, especially those involving perineal or vaginal trauma. Restrictive use of episiotomy has been shown to reduce the risk of more severe tears and postpartum perineal pain. When perineal repair is required, a continuous, knotless suturing technique with absorbable synthetic suture decreases postpartum analgesia use as well as dyspareunia at 12 months.
- Postpartum hemorrhage occurs in 4% of all vaginal deliveries, and is defined as greater than 500 mL of blood loss in the first 24 hours. It may also be defined as blood loss significant enough to cause hemodynamic instability. The causes of postpartum hemorrhages may be broken down into four categories:
  - 1. Tone: Tone refers to uterine atony, and is responsible for 70% of postpartum hemorrhages. Uterine massage, and the

- use of agents such as oxytocin, methylergonovine, and carboprost should be considered to stimulate uterine contractions.
- 2. Trauma: Perineal, cervical, and vaginal lacerations, as well as uterine rupture or inversion, should be sought as a source of bleeding. These sources account for 20% of cases of postpartum hemorrhages.
- 3. Tissue: Retained tissue or, less commonly, invasive placenta causes up to 10% of postpartum hemorrhages. In some cases, manual removal of the placenta is required, and in the case of invasive placenta (placenta accreta, increta, or percreta), surgical consultation and intervention are required.
- 4. Thrombin: Coagulation disorders are rare causes (<1%) of postpartum hemorrhages, as most of these are identified previously, allowing for planning and management prior to vaginal delivery. Management of postpartum hemorrhage includes early recognition, immediate fluid resuscitation, and identification and treatment of the underlying cause.
- Endometritis can occur after an uncomplicated vaginal delivery.
   It is more common if uterine manipulation, instrumentation, or prolonged labor and rupture of membranes have occurred.
   Retained products of conception (placenta or membranes) also increase the risk of infection.
- Uterine inversion is an infrequent complication of vaginal delivery. Uterine inversion is associated with fundal placentas, uterine atony, and congenital weakness of the uterus. Management begins with calling for assistance, including general anesthesia, and immediately attempting to replace the uterus. If possible, it should be replaced without removing the placenta. If the uterus is not replaceable immediately, there is an 85% to 90% success rate of replacing the uterus with tocolysis. (Oxytocin should be discontinued and the uterus relaxed with IV beta-mimetic medications or magnesium sulfate [preferred].) The remaining 15% to 20% of patients will require general anesthesia for the abdominal relaxation needed for uterine replacement. After replacement, oxytocin should be restarted and the postpartum hemorrhage managed appropriately.
- A rare complication of vaginal delivery is amniotic fluid embolism (AFE), occurring in 1 of 20,000 pregnancies, with a mortality rate as high as 85%. AFE presents with rapid, unexpected respiratory distress and cardiovascular collapse, leading to disseminated intravascular coagulopathy (DIC), coma, and death. Rapid clinical diagnosis and aggressive intensive care unit (ICU) management can reduce mortality risk, but progression can be very rapid and difficult to reverse.

# **Fetal Complications**

The main risks to a fetus through the delivery process are trauma and hypoxia. Numerous problems can occur during the process, but most newborns survive delivery without complication. Following is a partial list of possible fetal complications:

- Respiratory distress
- Hemodynamic instability
- Neonatal sepsis
- Intracranial hemorrhage
- Brachial plexus damage
- Fractures (humerus and clavicle common)
- Asphyxia and associated problems

Management of these complications is beyond the scope of this chapter. Chapter 180, Neonatal Resuscitation, gives an overview of the acute treatment of emergent complications.

# POSTPROCEDURE MANAGEMENT

Unless delivered in a labor-delivery-recovery-postpartum (LDRP) room, the patient is transferred to a postpartum room approximately

2 hours after a normal spontaneous delivery. She remains there until discharged home approximately 2 days later.

While in the recovery stage, the patient should be regularly assessed for postpartum hemorrhage. This can be best evaluated with observation of the perineum, which should be absent of continuous blood flow. The uterine fundus should be firm and below the umbilicus. The patient should remain hemodynamically stable with normal vital signs before transfer. If concern for postpartum hemorrhage or other complication exists, transfer to the postpartum floor should be delayed.

After being taken to the postpartum room the patient should be assessed at least daily by a clinician. The assessment should include evaluation for vaginal bleeding or infection. The patient should be instructed regarding the normal amount of vaginal bleeding after delivery (lochia rubra) and return to normal function. She should also be monitored for signs and symptoms of postpartum blues and depression, mastitis, venous thromboembolism, constipation, and sleep disturbance. Pain control is generally obtained with any of the following: acetaminophen, ibuprofen, naproxen, and acetaminophen with codeine. For constipation, Milk of Magnesia, docusate sodium, Dulcolax suppository, or psyllium may be helpful. Routine blood count measurements are generally not indicated following an uncomplicated vaginal delivery. Prior to discharge, birth control measures should be discussed and instructions given.

### POSTPROCEDURE PATIENT EDUCATION

On discharge from the hospital, patients should be given specific instructions about their medications and other postpartum care. Any and all questions should be answered. Whether patients are breast-feeding or not, new mothers will require instructions for breast care. They should also be instructed about sitz baths, Peri-Pads, and other perineal care. Inform them about when to call the clinician. Pelvic rest should be maintained for at least 1 month. The follow-up appointment should be 4 to 6 weeks after the delivery.

### INTERPRETATION OF RESULTS

The most objective way to assess for fetal acidosis at birth is by analysis of umbilical cord blood at delivery. This information can be useful in differentiating those newborns who are "depressed" (have low Apgar scores) from those who are truly acidotic at delivery. The pH,  $PCO_2$ ,  $PO_2$ ,  $CO_2$ , hemoglobin, and oxygen content of the blood can be measured, and the bicarbonate concentration, oxygen saturation, and base excess/deficit can be calculated from these measurements. Table 177-2 shows normal values for these measurements.

The most useful value for assessing fetal condition is pH. Fetal pH is typically 0.1 unit lower than maternal pH. The mean arterial fetal pH is 7.28, with the 5th and 95th percentiles at 7.14 and 7.40, respectively. The risk of neonatal morbidity is inversely related to pH, with the highest risk for those with pH less than 6.9. In several studies, umbilical artery pH lower than 7 was predictive of neonatal morbidity (e.g., seizures). However, it should be noted that the majority of newborns with pH less than 7 were admitted to the regular newborn nursery and had an uncomplicated neonatal course. Umbilical artery  $PO_2$  is not predictive of any adverse neonatal outcome.

<b>TABLE 177-2</b>	Normal	Ranges fo	or Cord Blood
Gas Analysis			

рН	7.27 to 7.28
PCO <sub>2</sub> (mm Hg)	49.2 to 50.3
$HCO_3^-$ (mEq/L)	22 to 23.1
Base excess (mEq/L)	-2.7 to $-3.6$

The calculated base deficit or excess is also useful, because metabolic acidosis leads to excess production of acid, or a negative base excess (base deficit). A base deficit greater than 12 mmol/L is predictive of neonatal complications. Fetal blood gas analysis does not distinguish between potential causes of fetal acidosis; fetal, placental, and maternal factors could all play a role.

### **CPT/BILLING AND CODING**

- 59400 Global vaginal delivery (routine obstetric care, including antepartum care, vaginal delivery [with or without episiotomy, and/or forceps] and postpartum care)
- 59409 Vaginal delivery *only* (with or without episiotomy, and/or forceps)
- 59410 Vaginal delivery *only* (with or without episiotomy, and/or forceps) and postpartum care (no antepartum care)
- 59430 Postpartum care only
- 59610 Global VBAC delivery (routine obstetric care including antepartum care, vaginal delivery [with or without episiotomy and/or forceps] and postpartum care after previous cesarean delivery)
- 59612 Vaginal delivery only, after previous cesarean delivery
- 59614 Vaginal delivery only, after previous cesarean delivery including postpartum care
- 59899 Unlisted procedure maternity care and delivery (induction, etc.)

**NOTE:** A patient who is admitted for labor that is post-term, induced, augmented, or otherwise complicated (blood pressure problems, arrest of labor, fetal distress, etc.) is not included in a routine delivery. These types of deliveries should be coded with routine inpatient or outpatient evaluation and management codes (e.g., 99221 to 99223).

- 99291 Critical care, evaluation of the critically ill or critically injured patient, first 30 to 74 minutes (e.g., preeclampsia, placenta previa or abruptio, postpartum hemorrhage, pulmonary or amniotic fluid embolism)
- 99292 Each additional 30 minutes
- 99356 Prolonged physician service in the inpatient setting, requiring direct (face-to-face) patient contact beyond the usual routine service, but not in critical care unit (e.g., maternity fetal monitoring for high-risk delivery or other physiologic monitoring); first hour
- 99357 Each additional 30 minutes
- 99358 Prolonged evaluation and management service before and/or after direct face-to-face patient care (e.g., review of extensive records and tests, communication with other professionals and/or patient/family); first hour
- 99359 Each additional 30 minutes

**NOTE:** A good reference for coding is provided by the American Academy of Family Physicians at http://www.aafp.org/online/en/home/practicemgt/codingresources/codingob.html.

### **ICD-9-CM DIAGNOSTIC CODES**

Codes 630 to 677 cover the "Complications of Pregnancy, Childbirth and Puerperium." Commonly used codes at the time of delivery are shown in the following list. The fifth digit is required for codes 640 to 676. For these codes the following applies:

- indicates unspecified as to episode of care
- 1 indicates delivered with or without mention of antepartum condition
- 2 indicates delivered, with mention of postpartum condition
- 3 indicates antepartum condition or complication
- 4 indicates postpartum condition or complication

645.1	Post-term pregnancy (40–42 weeks)
645.2	Prolonged pregnancy (>42 weeks)
649.1	Obesity complicating pregnancy, childbirth, or the
	puerperium
650	Normal delivery (not to be used with any other code in
	630 to 676, fourth and fifth digits not required)
654.2	Previous cesarean section
656.3	Fetal distress
658.0	Oligohydramnios
658.1	Premature rupture of membranes
659.2	Pyrexia in labor
659.4	Grand multiparity
659.7	Abnormality in fetal heart rate or rhythm (e.g., fetal bra-
	dycardia or tachycardia)
662.0	Prolonged first stage of labor
662.2	Prolonged second stage of labor
663.0	Prolapse of cord
663.1	Cord around neck, with compression
664.1	Perineal laceration, second degree
664.2	Perineal laceration, third degree
664.3	Perneal laceration, fourth degree
666.12	Postpartum hemorrhage
667.12	Retained placenta/membranes

#### **USEFUL CONTINUING EDUCATION**

#### Advanced Life Support in Obstetrics (ALSO)

This course provides practice for both the cognitive and the manual skills for simple or complicated deliveries. Lifelike pelvic and infant mannequins allow the learner to practice in a calm environment, even using forceps or vacuum-assisted delivery equipment. Courses are taught throughout the United States as well as internationally. More information can be found at www.aafp.org/also.

#### Family-Centered Maternity Care Conference

This course is designed to provide state-of-the-art, evidence-based education in the knowledge, training, and skills of caring for patients and their families during pregnancy and the birth process. It is organized by the American Academy of Family Physicians (AAFP). More information is available at http://www.aafp.org/.

## **DELEE SUCTIONING**

David B. Bosscher

Suctioning with a DeLee suction device may clear the upper airway of the neonate. Meconium is present in the amniotic fluid in 9% to 20% of deliveries. For many years, it was thought that DeLee suctioning of the oropharynx and stomach carried out before delivery of the neonate's chest would prevent meconium aspiration syndrome, and there were studies to support this practice. It is now known that some infants aspirate before delivery and therefore no intrapartum intervention can prevent all meconium aspiration. Although DeLee suctioning after delivery of the anterior shoulder and before delivery of the chest (i.e., intrapartum suctioning, before the neonate's first breath) may prevent further meconium aspiration with the first breath, it is no longer part of neonatal resuscitation guidelines (published in 2005; see Chapter 180, Neonatal Resuscitation). This change is because one large, randomized multicenter trial (Vain and colleagues, 2004) found no benefit to performing such an intrapartum procedure. That said, many experts in both obstetrics and pediatrics still recommend suctioning the oropharynx or nasopharvnx if the amniotic fluid or infant is meconium stained. Most agree that nothing more needs to be done if the infant is vigorous (defined by strong respiratory efforts, a heart rate >100 beats per minute, and good muscle tone), and this is supported by randomized, controlled trials. Most also agree that further intervention, such as endotracheal intubation and direct suctioning of the trachea (usually with a meconium aspirator applied to the endotracheal tube as the endotracheal tube is withdrawn) is indicated in those infants who are not vigorous, especially premature infants. (This assumes that the equipment and expertise are available and that, if so, and if at all possible, endotracheal suctioning should occur before stimulating these infants.)

#### **INDICATIONS**

- To help clear secretions in the newborn, including meconiumstained secretions, before stimulation (however, this should not delay more definitive endotracheal suctioning in the nonvigorous infant)
- To help relieve respiratory distress in the newborn when the stomach is full or when regurgitated stomach contents partially occlude the airway (again, this should not delay more definitive endotracheal suctioning in the nonvigorous infant)
- To assist in the diagnosis of choanal atresia
- To help exclude certain types of tracheoesophageal fistula

**NOTE:** In some tertiary care hospitals, DeLee suctioning is performed by the nursing staff before stimulation, while the infant is under the warmer and awaiting the neonatal resuscitation team. In such a setting, hospital bylaws may require the presence of a resuscitation team whenever there is meconium staining.

#### **CONTRAINDICATIONS**

#### **Absolute**

- A neonate with known choanal atresia should not receive DeLee suctioning by the nasal route.
- As mentioned previously, DeLee suctioning should not delay more definitive resuscitative efforts such as direct endotracheal suctioning; however, equipment and expertise for this are not always immediately available.

#### Relative

Thick particulate meconium cannot be adequately suctioned with a DeLee suction device alone.

#### **EOUIPMENT AND SUPPLIES**

- A DeLee or similar suction device, 8 to 10 Fr (Fig. 178-1)
- A bulb syringe to clear the mouth and nasal openings
- Gloves, facial coverings, and other necessary items for the clinician to observe universal blood and body fluid precautions
- Mechanical or wall vacuum or suction

**NOTE:** Newborns have a high degree of vagal tone and the pharynx is heavily innervated by the vagus nerve. Excessive vagal stimulation in a newborn, such as from overstimulation of the pharynx, can result in secondary apnea, bradycardia, or distress.

#### **TECHNIQUE**

- 1. Prepare the equipment. First make certain that the large-diameter end of the DeLee device, the end that will be attached to the external vacuum or suction source, is functioning. This can be done by handing this end to an assistant, who should then attach it to the external vacuum source. Cover the thumb opening/occluder and listen for a change in the noise from the vacuum. This also ensures that the vacuum source is functioning. Human-powered suctioning is no longer recommended.
- Quickly clear the mouth and nose of the neonate with a bulb syringe.
- 3. Use your index finger to open the infant's mouth and to depress the back of the tongue. Using your other hand, gently unroll and insert the much smaller-diameter mouth end of the DeLee device into the mouth of the neonate. Attempts should be made to keep this end as sterile as possible.
- 4. Slowly advance the catheter into the oropharynx, then direct it down into the esophagus (hypopharynx) with your finger.

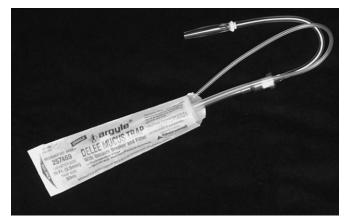

Figure 178-1 DeLee suction device.

- 5. Continue to advance the catheter until approximately 5 cm of its length remains outside the infant's mouth. The distal end is now in the infant's stomach.
- 6. Using a vacuum source that does not exceed 100 mm Hg, again apply vacuum to the suction end of the DeLee device by covering the thumb opening/occluder. After applying vacuum for a few seconds, slowly withdraw the catheter while continuously maintaining a vacuum. If time allows, use the same technique to suction the infant's nose.
- 7. After suctioning, check for any respiratory distress. Treat minor degrees of distress with proper positioning and oxygen administration, if necessary (see Chapter 180, Neonatal Resuscitation).
- As part of documenting the care of the newborn in the postdelivery period, always mention that DeLee suctioning was performed. Document any complications.

#### **COMPLICATIONS**

- Stimulation of the neonatal pharynx with any suction device during the first few minutes after delivery can evoke a vagal response and induce apnea, bradycardia, or fetal distress.
- Vigorous DeLee suctioning could cause trauma to the upper airways, the esophagus, and the stomach.
- In a neonate with a tracheoesophageal fistula, the DeLee suction device could enter the airway below the larynx, causing respiratory distress.
- Older DeLee suction devices, and even some of the newer ones that use human-powered suction, allow aspirated neonatal stomach contents to enter the mouth of the person applying suction. This method has the potential for spreading infectious diseases. A human mouth should not be used to apply suction on a DeLee. Newer models use mechanical or wall vacuum suction and are safer for the clinician; however, they are more cumbersome and difficult to use in a sterile field.

#### **CPT/BILLING CODES**

- 99431 History and examination of the normal newborn infant, initiation of diagnostic and treatment programs and preparation of hospital records
- 99436 Attendance at delivery (when requested by the delivering physician) and stabilization of newborn
- 99440 Newborn resuscitation; provision of positive-pressure ventilation and/or chest compressions in the presence of acute inadequate ventilation and/or cardiac output

99436 may be reported in addition to 99431 but may *not* be reported in addition to 99440.

#### **ICD-9-CM DIAGNOSTIC CODES**

- 656.83 Meconium passage during delivery
- 656.84 Meconium passage after delivery
- 763.84 Meconium passage during delivery, affecting newborn, excludes 770.11, 77.12, 779.84
- 768.6 Asphyxia, newborn, mild/moderate at birth
- 770.18 Newborn aspiration, 2000 to 2499 grams
- 770.19 Newborn aspiration, >2500 grams
- 770.11 Meconium aspiration, newborn, without respiratory symptoms
- 770.12 Meconium aspiration, newborn, with respiratory symptoms
- 770.84 Respiratory failure, newborn
- 770.85 Aspiration of postnatal stomach contents, newborn, without respiratory symptoms
- 770.86 Aspiration of postnatal stomach contents, newborn, with respiratory symptoms
- 770.87 Respiratory arrest, newborn
- 770.88 Hypoxemia of newborn
- 770.89 Other respiratory problems after birth
- 779.81 Bradycardia, newborn
- 779.84 Meconium staining, newborn
- 779.85 Cardiac arrest, newborn
- 792.3 Amniotic fluid, nonspecific abnormal finding

## SUBCUTANEOUS RING AND DORSAL PENILE BLOCK FOR NEWBORN CIRCUMCISION

Grant C. Fowler

The American Academy of Pediatrics has recommended routine use of analgesia for circumcision since 1999. A recent survey of residency program directors found that 97% of pediatric, family medicine, and obstetrics and gynecology programs that teach circumcision teach the administration of an anesthetic, either locally or topically. Therefore, the controversy about whether or not infants should receive analgesia or anesthesia for circumcision has ended. Previously, the controversy weighed whether the incompletely developed neonatal nervous system was capable of experiencing pain against the risk of anesthesia. Many clinicians chose not to use circumcision anesthesia, in part because of this controversy, but also owing to their lack of training or experience in the techniques available, the additional steps (and time) required to perform the procedure, and the time required for the anesthesia to take effect. However, with proper planning, the number of steps and the time required are minimal. In addition, studies have documented the safety of anesthesia as well as the improved outcomes in neonates.

Common analgesic and anesthetic techniques for circumcision include subcutaneous ring block, dorsal penile nerve block (DPNB). topical anesthesia (see Chapter 10, Topical Anesthesia), and precircumcision oral analgesics. Several studies have reported that the subcutaneous ring block is the most effective, and it has therefore basically replaced DPNB as the anesthetic technique of choice. (This is different in adults, where the most effective anesthesia for office circumcision is probably a combination of all three.) This chapter discusses subcutaneous ring block, DPNB, and an alternative technique of DPNB using a single injection. All three techniques appear to be more effective than topical or oral anesthesia, and no major complications have been reported with any of these methods. Studies have found that anesthetized infants show less crying, tachycardia, and irritability and exhibit fewer behavior changes for the 24 hours after circumcision. They also have less variability in oxygen saturation and blood pressure during the procedure and lower serum cortisol levels after the procedure. One small study in children found that lidocaine-prilocaine (eutectic mixture of local anesthetics, or EMLA) cream applied an hour before the ring block reduced the pain of needle puncture. However, because most clinicians are not able to prepare a newborn an hour before its circumcision, they would probably rely on the nursing staff to apply the cream. Conversely, in adults and children who are about to undergo office circumcision under local anesthesia, waiting an hour for the lidocaine-prilocaine cream to take effect may be very worthwhile.

#### **INDICATION**

Parental desire (however, parents should be encouraged to consent to this procedure in any healthy newborn undergoing circumcision).

#### **CONTRAINDICATIONS**

- Known hypersensitivity to anesthetic
- A known bleeding disorder (relative contraindication)

#### **EQUIPMENT**

- 1% lidocaine without epinephrine
- 1-mL syringe with 27-gauge needle (some tuberculin syringes come with this combination). If the needle is removable, using a 30-gauge needle to administer the anesthetic may minimize bleeding and discomfort.
- Alcohol wipe
- Infant restrainer (papoose board or Circumstraint) if assistant not available to hold infant
- Lidocaine–prilocaine (EMLA) cream (optional)

**NOTE:** There is a risk of methemoglobinemia after use of EMLA cream in certain situations. However, this risk is minimized with circumcision because it is used only once on intact skin and not with other drugs known to cause methemoglobinemia (e.g., nitric oxide).

#### PREPROCEDURE PATIENT PREPARATION

Discuss the risks, benefits, and alternatives with the parents, and obtain informed consent. Most clinicians combine this consent with the circumcision consent form.

#### **TECHNIQUE**

Before the procedure, note the anatomy as shown in Figure 179-1. Consider giving the infant a few swallows of glucose water or a sugar-coated pacifier to minimize distress. In a warm room, have an assistant hold the infant or place the infant's legs in restraints. Fold back the diaper to expose the penis.

**NOTE:** As the clinician becomes more comfortable performing ring block or DPNB, time may be saved by performing the procedure

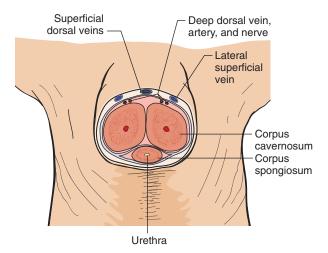

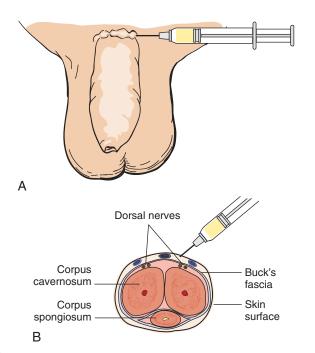

Figure 179-1 Anatomy of the penile root (cross-section).

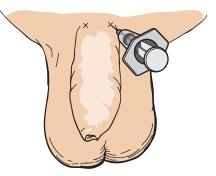

before the infant is surgically prepared. This allows time for the anesthetic to take effect while other preparations are being made.

#### **Subcutaneous Ring Block**

- 1. Prepare the skin both at the base of the penis as well as around the penis with an alcohol pad. Using aseptic technique and stabilizing the penis by gentle, slightly downward or ventral traction, insert the needle into the lateral side of the penis at the base (Fig. 179-2). Staying superficial to Buck's fascia, place a subcutaneous bleb of lidocaine. Then advance the needle circumferentially around the base of the penis while injecting. A couple of punctures may be necessary to accomplish this.
- 2. After completing a 180-degree half-circle, the same procedure is followed on the opposite side of the penis. A maximum of 1 mL of lidocaine should be used to complete the 360-degree

**Figure 179-2** Subcutaneous ring block. **A,** Needle is inserted at base of penis and a subcutaneous bleb of lidocaine is placed. A 360-degree ring of anesthesia is completed around the penis. **B,** Cross-section of penis at base showing paired dorsal nerves deep to Buck's fascia.

**Figure 179-3** Injection sites and direction of needle for administering dorsal penile nerve block.

circumferential ring. Intravascular injection can be avoided by frequently aspirating with the syringe to check for any blood return prior to each ¼ mL injected.

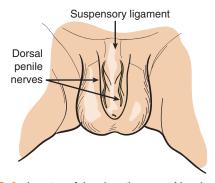

#### **Dorsal Penile Nerve Block (Two Techniques)**

#### Standard Technique

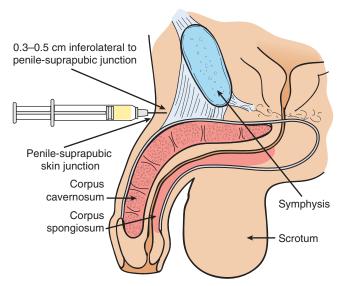

- 1. Using an index finger, palpate the lateral side of the penis to determine the depth of the root of the penis, which is usually about 0.75 to 1 cm beneath the skin surface. Often it is about the size, shape, and consistency of a large blueberry and is located just under the symphysis pubis.
- 2. Prepare the skin at the base of the penis with an alcohol pad. Using aseptic technique and stabilizing the penis by gentle, slightly downward or ventral traction, insert the needle at the 1 o'clock position (the dorsal or cranial direction being the 12 o'clock position, and the ventral direction being the 6 o'clock position) and direct it posteromedially (Fig. 179-3). Insert to a depth of 0.3 to 0.5 cm, which corresponds to 0.5 to 0.7 cm distal to the penile root, and this is slightly proximal to where the dorsal nerves branch (Fig. 179-4). The tip of the needle should be freely movable, indicating that it is in loose connective tissue, and this should prevent injection into the corpus cavernosum. Taking care not to inject into a blood vessel (check by aspirating), inject 0.4 mL of lidocaine. Repeat the injection at the 11 o'clock position with another 0.4 mL of lidocaine. (Avoid exceeding a total of 0.8 mL of lidocaine.)
- 3. In the infant whose penile root is not palpable because it is embedded in pubic fat, the anesthetic can be injected at the same locations, depths, and directions but about 0.3 to 0.5 cm inferolateral to the penile–suprapubic skin junction (Fig. 179-5).

#### Alternative Technique Using Single Injection Site

 Instead of making two skin punctures (at the 11 and 1 o'clock positions), an alternative is to insert the needle at the 12 o'clock

**Figure 179-4** Location of dorsal penile nerves. Note branching begins after emergence from the suspensory ligament of the penis.

**Figure 179-5** Sagittal view through the perineum showing anesthetic injection in a posteromedial direction at a depth of 0.3 to 0.5 mm.

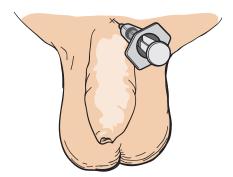

position and angle the needle toward the 11 and 1 o'clock positions. In other words, if the 12 o'clock position is where the dorsal skin of the penis reflects onto the abdomen (penile–suprapubic skin junction), insert the needle here and angle it toward the 1 o'clock position to a depth of about 0.5 cm. The tip of the needle should be freely movable, indicating that it is in loose connective tissue, and this should prevent injection into the corpus cavernosum. After aspirating to ensure the needle is not in a blood vessel, inject 0.4 mL of lidocaine.

2. Withdraw the needle until the tip is just below the skin surface, and then advance it again toward the 11 o'clock position (Fig. 179-6). The second injection can then be made, taking care not to exceed a total of 0.8 mL of lidocaine.

**NOTE:** A combination of ring block and DPNB has been demonstrated to be effective in adults undergoing office circumcision. Obviously, larger doses of lidocaine are used in adults.

#### **Notes Regarding Optimal Effects**

 One study in adults has found that using slower injection rates (i.e., longer injection times, such as 100 to 150 seconds) caused less pain than shorter injection times (40 to 80 seconds). Using a 30-gauge needle will not only slow the injection rate, it will increase overall patient comfort and cause less bleeding.

**Figure 179-6** Dorsal penile nerve block using a single injection site at the 12 o'clock position.

- Another study comparing plain and buffered lidocaine in newborns failed to demonstrate a difference in oxygen saturations, crying, heart rate, or any other measure of distress.
- Although some anesthesia will take effect in as little as 2 to 3 minutes, ideally 3 to 5 minutes should be allowed for the full effect of the anesthesia before performing circumcision. Conveniently, this is about the amount of time it takes to prepare and drape the infant and appropriately arrange the instruments.
- Avoid injecting air, which can cause pain.

#### **COMMON ERRORS**

- Insufficient time allowed for anesthetic to take effect
- Lidocaine injected in the wrong location

#### **COMPLICATIONS**

- Inadequate anesthesia
- Localized edema, bleeding, or hematoma at the injection site
- Local skin infection or necrosis
- Allergic reaction to lidocaine
- Systemic reaction to intravascular lidocaine
- Erythema and mild skin pallor observed with use of EMLA
- Penile necrosis (This is theoretical, because it has not been reported. Only lidocaine without epinephrine should be used because epinephrine can cause vasospasm of the penile arteries.)

#### **CPT/BILLING CODE**

64450-47 Nerve block, diagnostic or therapeutic, other peripheral nerve, anesthesia by surgeon

(A few insurers will pay for this as a separate procedure from the circumcision.)

#### **ICD-9-CM DIAGNOSTIC CODE**

V50.2 Routine or ritual circumcision, in absence of significant medical indication

## **NEONATAL RESUSCITATION**

Eric M. Hughes

The first few moments of a newborn's life can be the most critical. If needed, effective emergency care during this transition can prevent lifelong consequences. Proper resuscitation requires essential equipment and knowledge of necessary protocols before delivery. Prior knowledge of the gestational age of the newborn is helpful in anticipating the need for resuscitation. Low birth weight and premature delivery predispose infants to the need for resuscitative efforts.

#### **INDICATIONS**

Neonate with the following:

- Inadequate or ineffective respirations
- Inadequate heart rate
- Central cyanosis
- Other evidence of cardiorespiratory distress

#### **EQUIPMENT**

- Suction equipment, including a bulb syringe, mechanical suction device, suction catheters (6, 8, 10 French), pediatric feeding tube (8 French), and meconium aspirator (Fig. 180-1)
- Oxygen source with flowmeter, infant resuscitation bag (750 mL) with appropriately sized face masks, laryngoscope with no. 0 and no. 1 straight blades, and sterile newborn endotracheal tubes (2.5, 3, 3.5, and 4 mm), CO<sub>2</sub> monitor
- Drugs, including epinephrine 1:10,000 (0.1 mg/mL), naloxone (0.04 mg/mL), volume expanders (crystalloid or blood), and normal saline for injection
- Miscellaneous items, including a radiant warmer, pediatric stethoscope, needles (25, 21, and 18 gauge), syringes (1, 3, 10, 20 mL), adhesive tape (½-inch width), an umbilical catheter (3.5 or 5 French), and food grade heat-resistant plastic wrap

#### **TECHNIQUE**

As with all medical procedures, universal precautions against exposure to blood and other body fluids should be followed during this procedure. Initial measures, including proper positioning, drying, suctioning, and stimulation, should be provided to all newborns. Figure 180-2 is a flow diagram of the protocol for neonatal resuscitation that is explained in the following sections.

#### Positioning, Suction, and Stimulation

1. Prevent heat loss by placing the infant under a radiant heat source, then quickly drying him or her and removing the wet linen. (Recovery from acidosis is delayed by hypothermia.) Infants of low birth weight (<1500 g) need extra equipment and effort to keep them warm because the traditional radiant warmer and blankets are insufficient. The body, but not the head, of the neonate may be covered with food grade heat-resistant plastic

- wrap in addition to providing radiant heat. Use of this technique requires constant monitoring to assure overheating does not occur.
- 2. Open the airway by positioning the infant on its back with the neck slightly extended. Avoid extreme hyperextension or flexion of the infant's neck, which may diminish airflow.
- 3. Clear the airway by suctioning the mouth, then the nose, with a bulb syringe or mechanical device (suction catheter; see Chapter 178, Delee Suctioning). If mechanical suction is used, pressure should not exceed 100 mm Hg. Deep suctioning of the oropharynx may produce a vagal response and cause bradycardia and apnea. Infants with meconium-stained amniotic fluid should no longer be suctioned with mechanical devices after the head is delivered and prior to the body being delivered. Direct tracheal suctioning should be carried out only if the newborn has absent or depressed respirations, a heart rate below 100 bpm, or poor muscle tone. A meconium aspirator is very helpful in performing this procedure (see Fig. 180-1). This unique piece of equipment is used only for neonates. One end of the device is for a neonatal endotracheal tube, the other end is for suction, and the top hole is for the operator's thumb.
- 4. Promote respiratory activity by providing tactile stimulation (e.g., slap the sole of the foot or gently rub the back).

#### **Initial Assessment**

- 1. Assess the infant's respiratory status, heart rate, and color.
- Infants with adequate respiratory and cardiac function (good ventilation and heart rate >100 bpm) and with no evidence of central cyanosis can be merely observed.
- 3. Infants with depressed respiratory function (shallow, slow, or absent respirations), an abnormal heart rate, or central cyanosis should undergo further resuscitation.

#### **General Guidelines of Resuscitation**

As with all resuscitations, the order of importance is airway, breathing, and circulation. The three cardinal indicators in neonatal resuscitation are respirations, heart rate, and color. In general, the initial assessment should take no more than 30 seconds; should the need for further resuscitation occur, reassessment of interventions should occur every 30 seconds. Apgar scores should be determined and recorded at appropriate intervals. Special circumstances may arise and may be treated with procedures used in general pediatric resuscitation (e.g., chest tube for pneumothorax).

#### **Ventilation**

1. Ventilatory insufficiency produces the majority of respiratory and circulatory abnormalities during the newborn period. *Rapid* institution of ventilatory support in newborns with abnormalities of respiratory function or heart rate or central cyanosis maximizes the chances of a successful outcome.

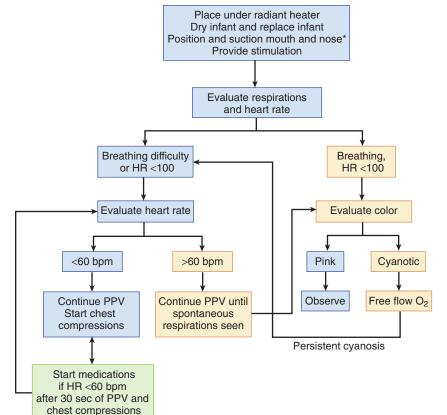

Figure 180-1 Meconium aspirator.

TABLE 180-1 Endotracheal Tube Selection					
Infant Weight (g)	Gestation Age (wk)	Endotracheal Tube Size (mm)			
<1000 1000–2000 2000–3000 >3000	<28 28–34 34–38 >38	2.5 3 3.5 3.5–4			

- 2. Positive pressure ventilation (PPV) with 100% oxygen is indicated for infants with inadequate respiratory effort or a heart rate less than 100 bpm. Free-flow oxygen administration may be adequate for the infant with central cyanosis if respiratory function is adequate and the heart rate is over 100 bpm. (The cause for cyanosis should be sought.) If central cyanosis persists despite oxygen administration, PPV should be applied.
- 3. PPV is usually accomplished with a bag and mask, using either a self-inflating bag or an anesthesia bag. A good seal should be maintained by using an appropriately sized face mask with a cushioned rim. A pressure gauge or pop-off valve should be used to ensure adequate ventilatory pressures.
- 4. Ventilate the infant at a rate of 40 to 60 breaths per minute with a tidal volume of 6 to 8 mL/kg. Adequate ventilation is verified clinically by observing bilateral symmetrical chest expansion and the presence of bilateral breath sounds. Inadequate ventilation may indicate an inadequate face mask seal, a blocked airway, or inadequate ventilation pressure. After initial ventilations, pressures of less than 30 to 40 cm H<sub>2</sub>O (20 to 25 cm H<sub>2</sub>O for preterm infants) should be adequate.
- 5. Perform an endotracheal intubation when prolonged PPV is required, bag and mask ventilation is ineffective, chest compres-

- sions are used, endotracheal delivery of medication is necessary, or diaphragmatic hernia is suspected. Select an endotracheal tube of appropriate size (Table 180-1) and insert it under direct visualization using the laryngoscope. The tip should rest above the tracheal bifurcation. Appropriate endotracheal tube location is verified clinically by the presence of bilaterally symmetrical breath sounds and confirmation of expired CO<sub>2</sub>. Most clinicians also confirm endotracheal tube placement with a chest radiograph.
- Oral airways are rarely required during neonatal resuscitation but are indicated for bilateral choanal atresia, Pierre Robin syndrome, and when necessary for adequate ventilation.
- 7. Use of a laryngeal mask airway (LMA) (Fig. 180-3) can be an acceptable alternative when bag-mask ventilation and endotracheal intubation have failed. (The LMA is a substitute in certain cases for traditional endotracheal intubation.) The LMA should be used only by properly trained personnel and is not considered a routine substitute for endotracheal intubation.
- 8. Gastric catheter placement (8 French) is indicated in prolonged resuscitation efforts to prevent stomach distention, a frequent problem in newborns who are being ventilated by mask

**Figure 180-2** Resuscitation flowchart. bpm, beats per minute; HR, heart rate; PPV, positive pressure ventilation. \*Consider endotracheal intubation if meconium present and infant not vigorous.

**Figure 180-3** Laryngeal mask airway. (Courtesy of Legend Medical Devices, Inc.)

#### **Chest Compressions**

- 1. Administer chest compressions if the infant's heart rate is less than 60 bpm after adequate PPV for 30 seconds. Chest compressions can be accomplished with the thumbs placed on the sternum and the hands encircling the chest (preferred method), or with the tips of the middle and index fingers (Fig. 180-4). Chest compressions should be applied to the lower third of the sternum. The sternum should be depressed one third of the anteroposterior dimension of the chest, rather than an exact depth of compression. The compression depth must be adequate to produce a palpable pulse.
- 2. Chest compressions should be administered at a ratio of 3:1 with PPV, at a rate of 90 compressions and 30 ventilations every minute. Reassess the pulse every 30 seconds. The umbilical cord stump is a convenient location to palpate the pulse.
- 3. Continue chest compressions until the spontaneous heart rate is 60 bpm or higher (see Fig. 180-2).

#### **Medications**

Table 180-2 summarizes the medications used in neonatal resuscitation. Administer medications for asystole or if the heart rate remains less than 60 bpm after adequate PPV and chest compressions for a minimum of 30 seconds. Medications may be administered through the umbilical vein with a 3.5- or 5-French umbilical catheter placed

just below the skin level. (See Chapter 184, Umbilical Vessel Catheterization.) Alternative access can be obtained through a peripheral vein or, in the event that no other access is available, by intraosseous access (see Chapter 198, Intraosseous Vascular Access). Intraosseous access can be very difficult to obtain in premature infants. Alternative routes of administration (endotracheal, intramuscular, or subcutaneous) are available for some medications.

#### **Termination of Resuscitation**

Discontinuation of resuscitative efforts may be appropriate if resuscitation of an infant with cardiorespiratory arrest does not produce spontaneous circulation within 10 minutes. Resuscitation of newly born infants after 10 minutes of asystole is also very unlikely to result in survival or survival without severe disability. Those involved in neonatal resuscitation should pursue local discussions to formulate guidelines consistent with local resources and outcome data.

#### POSTPROCEDURE PATIENT MANAGEMENT

- Maintain careful monitoring in an appropriately staffed intensive care unit (or arrange transfer to such a facility).
- Continue evaluation with serial arterial blood gases, frequent determination of fluid and electrolyte status, chest radiographs, and other modalities as indicated by clinical findings.
- Completely document the resuscitation effort in the medical record.
- Discuss situation with parents.

#### **COMPLICATIONS**

#### Suction

- Vagal response (bradycardia or apnea)
- Hypoxia

#### **Ventilation**

- Pneumothorax
- Hypoxia resulting from inadequate ventilation

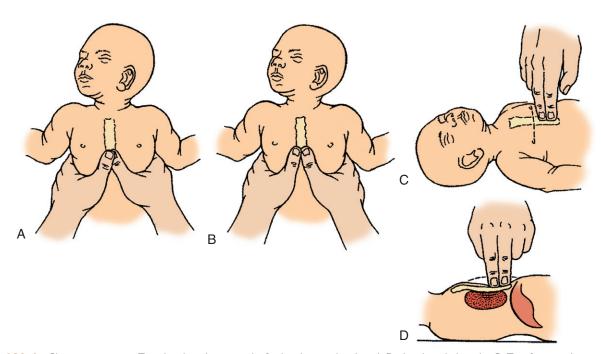

Figure 180-4 Chest compression. Two-thumb technique with, **A**, thumb over thumb and, **B**, thumbs side by side. **C**, Two-finger technique. **D**, Chest compression depth is one third to one half of the anteroposterior diameter of the chest or one third of the depth of the chest.

TABLE 180-2 Med	TABLE 180-2 Medications Used for Neonatal Resuscitation				
Medication	Indication	Dose	Route of Administration		
Epinephrine	Asystole or HR <60, despite adequate PPV and chest compressions for 30 sec	0.1–0.3 mL/kg of a 1:10,000 solution or 0.01–0.03 mg/kg	IV (preferred) or ET; can repeat every 3–5 min		
Volume expander (crystalloid or blood)	Evidence of acute blood loss with signs of hypovolemia, or failure to respond to resuscitation or signs of shock	10 mL/kg	IV over 5–10 min		
Naloxone	History of maternal narcotic administration within 4 hr of delivery; not recommended for initial efforts, heart rate and color should be restored by supporting ventilation first	0.1 mg/kg	IV preferred, IM		

ET, endotracheal; HR, heart rate; IM, intramuscular; IV, intravenous; PPV, positive pressure ventilation.

Complications from intubation (see Chapter 213, Tracheal Intubation)

# Newborn Circumcision and Office Meatotomy

Ronald D. Reynolds • Grant C. Fowler

Newborn circumcision is the most common surgical procedure performed in the United States, yet controversy exists over the need for the procedure. Studies have shown a lower incidence of urinary tract infection (UTI), phimosis, paraphimosis, balanoposthitis, and some sexually transmitted infections (STIs), including human immunodeficiency virus (HIV), in circumcised men. Circumcision clearly helps prevents penile cancer and may decrease the risk of cervical cancer in the sexual partner. However, some of these problems (i.e., penile cancer, UTIs, foreskin problems, and HIV infection) are rare even in uncircumcised men.

In developed countries where it is much less common for males to be circumcised, there is a low incidence of foreskin problems later in life. Behavioral factors also appear to be far more important than circumcision status in regards to the acquisition of STIs and HIV infection. Therefore, the decision to circumcise is not currently based on scientific evidence. Rather, this decision is generally made based on cultural, familial, or ethnic preference.

There is controversy in the literature regarding the cost effectiveness of newborn circumcision. Authors of a retrospective cost–benefit analysis of almost 15,000 newborn boys born in 1996 and insured by Kaiser Permanente Northern California (a large health maintenance organization) concluded that neonatal circumcision can be achieved at basically no cost. When total costs of newborn circumcision were weighed against total medical costs of not having it, the costs were basically equal. This was largely because postneonatal circumcision costs were about 10 times more than neonatal circumcision costs (\$1921 per child versus \$165 per newborn), and circumcision was eventually medically indicated in 9.6% of uncircumcised boys. However, other cost–benefit analysis studies have reached opposite conclusions. Also, there is controversy in the literature as to whether the percentage of newborns undergoing circumcision is increasing. If that is the case, it may start becoming more of a norm.

Clinicians performing circumcision are encouraged to remain current with guidelines and the scientific evidence. The American Academy of Pediatrics (AAP) circumcision position from March 1999, endorsed by the American College of Obstetricians and Gynecologists (ACOG) in 2001, and reaffirmed in 2005, reads as follows:

Existing scientific evidence demonstrates potential medical benefits of newborn male circumcision; however, these data are not sufficient to recommend routine neonatal circumcision. In circumstances in which there are potential benefits and risks, yet the procedure is not essential to the child's current well-being, parents should determine what is in the best interest of the child. To make an informed choice, parents of all male infants should be given accurate and unbiased information and be provided the opportunity to discuss this decision. If a decision for circumcision is made, procedural analgesia should be provided.

Of note, 97% of pediatric, family medicine, and obstetrics and gynecology residency programs that teach circumcision teach the administration of an anesthetic, either locally or topically. Common methods of analgesia administration include subcutaneous ring block, dorsal penile nerve block (DPNB; see Chapter 179, Subcutaneous Ring and Dorsal Penile Block for Newborn Circumcision), topical anesthesia such as lidocaine-prilocaine cream (also known as eutectic mixture of local anesthetic, or EMLA; see Chapter 10, Topical Anesthesia), and precircumcision oral analgesics. Although studies have shown lidocaine-prilocaine cream to be helpful, injected blocks appear to be more effective, and the ring block is more effective than a DPNB. Studies have shown that infants anesthetized with a block cry less, are less likely to have tachycardia, are less irritable, and have fewer behavior changes during the 24 hours after the procedure. They also have less variability in oxygen saturation and blood pressure during, and lower serum cortisol levels after, the procedure.

Three techniques of newborn circumcision are common in the United States: Mogen, Gomco, and Plastibell. Most clinicians continue to use the technique they were taught in their training. Both Gomco and Plastibell require a dorsal slit and considerable manipulation to prepare the foreskin for excision, and result in removal of a cylindrical sleeve of tissue. Both techniques carry the risk of removing too much tissue from the ventral side. In addition, Plastibell leaves behind a foreign body that may contribute to infection. One study comparing Gomco with Plastibell indicated that there was not only a higher rate of infection with Plastibell but also a slightly higher rate of bleeding.

Most clinicians who learn to use the Mogen clamp tend to prefer this technique because it is quicker and simpler, and it follows the angle of the corona so as to avoid removing excess tissue ventrally. At least two studies (Kurtis and colleagues, 1999; Kaufman and colleagues, 2002) comparing the use of the Mogen with the Gomco technique found that the Mogen procedure took about half the time and seemed to cause less discomfort (however, discomfort may be a moot point when anesthesia is used). Contrary to popular belief, the Mogen clamp is not a guillotine. It is simply a crushing device with a narrow slot that, when used appropriately, does not allow entry of the glans into the slot.

One apparent complication of circumcision is meatal stenosis (i.e., it is very rare in uncircumcised boys). Whether circumcision or a chronic inflammatory process due to superabsorbent disposable diapers, ammonia dermatitis, or inadequate parental postprocedure care is to blame is yet to be determined. In the last edition of this text, a technique for newborn meatotomy was included; however, there are few data suggesting that such a procedure might decrease the later incidence of meatal stenosis. (And it must be very rare or it would be more common in uncircumcised men.) This scarcity of data is partially because it is difficult to define meatal stenosis in a

newborn. It is usually diagnosed later in life, at the time of toilet training or even later, because of its complications (e.g., painful urination that may require straining or standing, difficulty aiming stream, blood spotting in underwear). To make the diagnosis may require observed voiding (i.e., pinpoint meatus and a dorsally deflected, very fine caliber, forceful urine stream with a long voiding distance) because the appearance of the glans may be somewhat normal and thereby misleading. However, newborn meatotomy is included again in this edition because the risk of such a procedure is minimal compared with potential benefits (e.g., repair in an older male patient can be somewhat psychologically traumatic). Also, in certain situations, newborn meatal stenosis is obvious and because the infant is already anesthetized for circumcision, it would seem prudent to repair it at that time.

After toilet training, a popular method of defining meatal stenosis is by what size feeding tube or pediatric urethral catheter can be easily inserted. Because meatal stenosis is a possible complication of newborn circumcision, it seems appropriate to also include a technique for later repair (i.e., office meatotomy) in this chapter. Although it might seem somewhat psychologically traumatic to repair meatal stenosis under mere topical anesthesia, boys having difficulty with urination may be very motivated to cooperate, especially if assured of the adequacy of topical anesthesia. Pediatric sedation may also be useful (see Chapter 7, Pediatric Sedation and Analgesia).

#### **ANATOMY**

The neonatal foreskin is composed of three layers: skin, loose subcutaneous tissue, and mucosa. At birth, the foreskin mucosa is adherent to the glans penis, with just a small distal opening to allow for urination. The ventral side of the mucosal surface has the highest density of nerve endings. A band of tissue called the *frenulum* attaches the foreskin along the ventral side of the penis and ends distally near the urethral meatus. The frenulum contains a small artery.

#### **CIRCUMCISION**

#### Indication

Parental desire is the only necessary indication for circumcision.

#### **Contraindications**

#### Absolute

- Hypospadias, epispadias, or megaurethra (the foreskin is used for later repair)
- Unusual-appearing genitalia
- Inability to determine the sexual phenotype of the child (ambiguous genitalia)

#### Relative

- Age younger than 12 hours (physiologic adaptation requires 12 to 24 hours)
- Age greater than 6 to 8 weeks
- Severe illness
- Prematurity (until the child is ready for discharge from the hospital)

#### **Precautions**

If there is a family history of bleeding problems, appropriate laboratory studies should be performed before the procedure. If the mother is thrombocytopenic, the infant's platelet count should be checked.

By the age of 6 to 8 weeks, maternal clotting factors have been metabolized, possibly predisposing the infant to increased blood loss. The foreskin may also develop significant edema after defining the

plane and breaking up adhesions between the glans and the foreskin, making it difficult to use the Gomco clamp or Plastibell.

#### **Preprocedure Patient and Parent Preparation**

Discuss the risks and benefits of the procedure with the parents. Informed consent is obtained and a patient teaching guide is given to the parents. (See patient education and patient consent forms available online at www.expertconsult.com.) The AAP has two brochures that may be used: (1) Circumcision: Information for Parents and (2) Care of the Uncircumcised Penis (see the Suppliers section). The parents are usually asked to leave the room during the procedure. If they desire to stay, they should be given the option to look away while the procedure is being performed because it can be disconcerting to some.

Because of the risks of regurgitation and aspiration, infants being circumcised should be at least 1 hour postprandial. Confirm that the infant has had at least one void since birth.

#### **Equipment**

#### **Equipment Common to All Techniques**

- Assistant for holding infant, infant restraint or papoose board (Circumstraint) with leg straps (e.g., Circumstraint), or circumcision chair (e.g., Stang)
- Anesthetic supplies: gloves, alcohol wipes, 1% plain lidocaine, 1-mL syringe, 30-gauge needle
- Sterile gloves
- Antiseptic solution (e.g., alcohol wipes, povidone-iodine, chlorhexidine) or swabsticks
- Sterile drape with 1-inch fenestration
- Sterile  $2 \times 2$  or  $4 \times 4$  gauze pads
- Three straight mosquito hemostats
- White petrolatum ointment (e.g., Vaseline)
- Disposable diaper
- Adequate light source
- Glucose water or sugar-coated pacifier (optional)
- Skin marking pen (optional)
- Flexible blunt probe (optional)
- Acetaminophen drops or solution (10 to 15 mg/kg) (optional)

#### Equipment for the Mogen Technique

• Mogen clamp, neonatal size (2.5-mm slot)

**NOTE:** The larger adult size is dangerous to use on a newborn because the glans can become trapped in the larger slot. The clinician should confirm that the neonatal size does not open more than 2.5 mm.

• No. 10 blade scalpel

#### Equipment for the Gomco Technique

- Straight scissors with one blunt tip
- Gomco circumcision clamps (1.1-, 1.3-, and 1.45-cm sizes)

**NOTE:** The most commonly used size is 1.3 cm. The 1.1-cm size is used for a very small infant, whereas the 1.45-cm clamp usually fits a large infant. Even larger sizes are available for children and adults.

- No. 10 blade scalpel
- Sterile safety pin (optional)

#### **Equipment for the Plastibell Technique**

- Straight scissors with one blunt tip
- Plastibell device (1.1-, 1.2-, 1.3-, and 1.4-cm sizes)

**NOTE:** Similar to the Gomco technique, 1.3 cm is the most commonly used Plastibell size.

Iris scissors

### **Equipment for Bleeding Complications in All Three Techniques**

- Topical epinephrine
- Topical hemostatic agent of choice (e.g., Gelfoam, Surgicel, silver nitrate; see Chapter 40, Topical Hemostatic Agents)
- 5-0 absorbable suture (chromic or catgut) on a taper-point needle
- Needle holder and suture scissors

#### Mogen Technique

- Consider using a skin marker to mark the coronal edge. Inspect
  the penis for abnormalities and for the location of the meatus
  on the glans. If epispadias or hypospadias is found, terminate
  the procedure because the foreskin may be used for later repair
  by a urologist.
- 2. The clinician should follow universal blood and body fluid precautions. If penile anatomy is normal, anesthetize the penis with a subcutaneous ring block (see Chapter 179, Subcutaneous Ring and Dorsal Penile Block for Newborn Circumcision). Consider doing the block with the infant still in his crib to allow time for the block to take effect while the rest of the surgical preparations are made. Position the infant appropriately in a warm room. An infant may experience discomfort when you extend his legs on an infant restraint board. As a result, special circumcision chairs have been developed for exposure of the penis without extension of the legs. If such a chair is not available, an assistant can hold the infant on a pillow with the knees flexed and legs abducted for adequate exposure. Most often, though, an infant restraining board is used. Leave the infant's arms free to minimize distress. Offer him a swallow or two of glucose water or a sugar-coated pacifier to calm him.
- 3. Using antiseptic solution or swabsticks, prepare the entire penis and a 1-inch area surrounding the penis. Wear sterile gloves when placing the fenestrated drape.
- 4. Grasp the very edge of the foreskin with hemostats at the 2 and 10 o'clock positions, taking care not to grasp the glans. (When describing the penis, use the dorsal midline as the 12 o'clock position. To identify the true dorsal midline, identify the ventral raphe at the frenulum, which is the 6 o'clock position, and consider the foreskin 180 degrees opposite it to be the 12 o'clock position [Fig. 181-1]. This orientation technique is important in case the penile shaft gets rotated.)
- 5. Place gentle traction on the foreskin by holding the two hemostats side by side in your nondominant hand. Gently insert the third hemostat with your dominant hand, closed and from below the grasping hemostats, at the 12 o'clock position between the foreskin and the glans. Advance to the depth of the coronal sulcus (Fig. 181-2). To ensure that the meatus is not entered, keep the foreskin tented up as this hemostat is

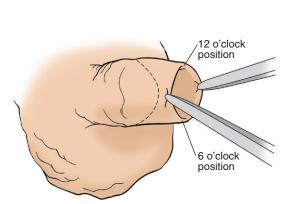

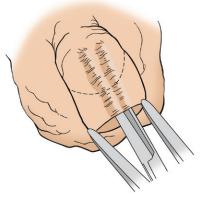

Figure 181-1 Using 6 o'clock as the ventral position of the frenulum, 12 o'clock is the dorsal midline position.

**Figure 181-2** Insert the third hemostat between the foreskin and the glans, tenting the foreskin as it is advanced. Here the surgeon is just beginning to open the hemostat to free the foreskin off the glans.

- advanced. Open this hemostat and sweep it clockwise and counterclockwise to free the foreskin off the glans. This may take a number of open—close cycles starting at different places around the corona. Do not free the area from the 5 to 7 o'clock positions (the frenulum) because it contains an artery. Do not dissect beyond the depth of the coronal sulcus. As an alternative to opening and closing a hemostat, a blunt probe may be used to free the foreskin off of the glans.
- 6. Tent the foreskin away from the glans by gently lifting the grasping hemostats. Ensure that no part of the glans is in the way. Advance the lower blade of the third hemostat between the glans and foreskin at the 12 o'clock position to a position no less than 5 mm distal to the coronal sulcus (Fig. 181-3). Do not apply traction to the grasping hemostats as this dorsal hemostat is applied or you will remove too much foreskin. Close and lock the hemostat in place.
- 7. Remove the two foreskin edge–grasping hemostats.
- 8. Using the thumb and index finger of your nondominant hand, pinch the free foreskin underneath the dorsal hemostat while curling your other fingers of the same hand around the handles of the hemostat. This pushes the glans back out of the way of the Mogen clamp. Release any traction on the hemostat and foreskin because traction on the frenulum can dorsally rotate the glans and bring the meatus into the path of the Mogen clamp. Maintain the pinch while the Mogen clamp is placed. The tips of the pinching fingers should be slightly proximal to the tip of the grasping hemostat.
- 9. Inspect the Mogen clamp to be sure that its joint is not loose and that it opens only 2.5 mm, then open it fully. Hold it so

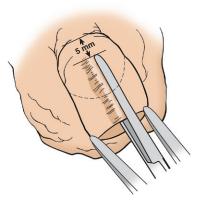

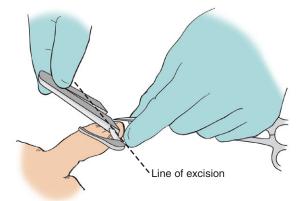

Figure 181-3 Place a dorsal hemostat with its tip 5 mm from the corona.

**Figure 181-4** Pinch the foreskin to push the glans back while advancing the Mogen clamp vertically along the angle of the corona.

that the open end of the slot is down and the flat surface faces you. With your dominant hand, advance the Mogen slot across the foreskin, starting immediately behind the tip of the dorsal hemostat (Fig. 181-4). Angle the Mogen's advancement to remove more foreskin dorsally than ventrally, following along the angle of the corona (dorsum of the glans). Slide the clamp across the foreskin as far as it will go easily. At this point, the use of previous skin markings can ensure that an adequate, but not excessive, amount of foreskin is removed.

- 10. Before locking the Mogen clamp, drop the foreskin pinch and attempt to move the glans beneath the slot. You should be able to move the glans freely for a few millimeters up and down and side to side. If the glans is not free, *do not* lock the Mogen clamp.
- 11. Lock the Mogen clamp by moving the bar across the slot and closing the cam lever fully.
- 12. Use the scalpel to cut the foreskin off flush with the flat surface of the Mogen clamp (Fig. 181-5). Discard the foreskin in a biohazard waste container.
- 13. Unlock and remove the Mogen clamp. There is no medical rationale for leaving the clamp on for any specific length of time.
- 14. Gently separate the crushed edges of the foreskin to liberate the glans. Grasp the penile shaft skin at the 3 and 9 o'clock positions to pull the crush line apart (Fig. 181-6). Be sure to separate fully to avoid the possibility of causing a paraphimosis. It is not unusual to have a few remaining attachments between the glans and the mucosal surface of the remaining foreskin next to the corona. The easiest way to divide these is to use the tip of a

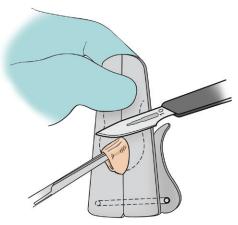

Figure 181-5 Excise the foreskin.

Figure 181-6 Liberate the glans with thumb pressure.

closed and locked hemostat to follow the coronal sulcus, but a blunt probe can also be used. Do not be too vigorous or try to free the frenular area because this will cause bleeding.

- 15. Check for hemostasis. To control any bleeding, apply pressure or topical epinephrine to the specific source. In rare cases of persistent bleeding, topical hemostatic agents can be applied with pressure to hasten clotting. Rarely will bleeding require suturing. In the event that it does, use an absorbable suture at the site of the bleeding, which is usually an arteriole. Persistent bleeding after circumcision is a common presenting sign for a factor-deficient bleeding disorder, such as hemophilia. If bleeding persists after following these described measures, obtain clotting studies and consider a hematology consultation.
- 16. Cover the glans with white petrolatum ointment, and reapply the diaper.
- 17. Administer an oral dose of acetaminophen (10 to 15 mg/kg) (optional).
- 18. Document the procedure and time in the chart. To ensure continued hemostasis, do not discharge the infant for about an hour after the procedure. The infant should also have urinated before discharge.

#### **Gomco Technique**

- 1. Choose an appropriate-size Gomco clamp, which is 1.3 cm for most newborns. (The bell diameter should be slightly larger than the diameter of the glans; although the bell should cover the glans completely, it should just barely cover it.) Carefully inspect the clamp. If the clamp was packaged disassembled, reassemble it in the sterile field. Because there is more than one manufacturer for Gomco clamps, make sure the reassembled clamp parts fit together properly. (Reassembled parts may be from different manufacturers.) Make sure the bell is the correct size for the clamp and that there are no defects. Lightly tighten the clamp with the bell in place. Make sure that no light can be seen around the bell where it meets the clamp at the base plate. This ensures a complete circumferential crush for optimal hemostasis. Next, verify that the top surface of the base plate is flat (it can become warped over time). Last, there should be at least 2 mm between the back of the lever arm and the base plate beneath the nut before tightening. This also ensures adequate clamping.
- 2. As in steps 1 through 5 of the Mogen Technique section, inspect the penis for abnormalities, consider marking the coronal edge, administer a penile subcutaneous ring block, position the infant (restrain if necessary), apply antiseptic and drapes, and free the foreskin from the glans.
- 3. As in step 6 of the Mogen Technique section, place a crushing dorsal hemostat at the 12 o'clock position, but apply it only to the distal third or half of the length of the foreskin (the total

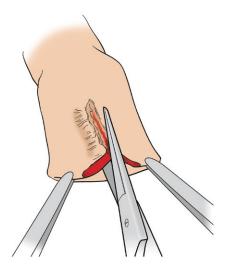

Figure 181-7 Incise the dorsal slit.

length of the foreskin extends from the foreskin edge to the coronal sulcus). This hemostat is not applied more proximal than 1 cm from the coronal sulcus. Make sure that the crushing hemostat contains both the mucosal and skin layers of the foreskin.

- 4. The hemostat can be removed immediately after crushing. Removal reveals a crushed straight line down the dorsal aspect of the foreskin; this crushed tissue has been devitalized and therefore will not bleed when cut. Insert the blunt blade of the scissors between the foreskin and the glans, underneath the crush line, and tent the foreskin with the two edge hemostats and this blade of the scissors. The crushed dorsal line should be thin enough to somewhat visualize the blunt blade through it when it is tented up. With the scissors placed in this manner, cut a dorsal slit down the center of the crush line (Fig. 181-7). Be careful to cut only in the crush line; do not extend laterally or past the apex of the crush line. Venturing beyond or outside the crush line will often result in unnecessary bleeding.
- 5. Separate the cut edges of the foreskin; this should then allow you to retract the foreskin back from around the glans. If, at this point, you cannot fully retract the foreskin, and it is due to an inadequate incision (and not due to adhesions), recrush a bit further dorsally on the foreskin and extend the dorsal slit. Lyse any remaining adherence between the foreskin and glans with the closed tips of a locked hemostat or the blunt probe. You should be able to fully reveal the sulcus behind the corona. Be very careful when dissecting between the 5 and 7 o'clock positions to avoid the frenulum and its artery.

**NOTE:** If the clinician notices hypospadias or epispadias after the dorsal slit has been made, terminate the procedure. After termination, if there is bleeding from the dorsal slit, whipstitch the edges or close the dorsal slit using fine chromic suture. Repair of penile congenital anomalies by a urologist may require foreskin tissue; do not remove any, if possible.

- 6. Place the bell of an appropriate-size Gomco clamp over the exposed glans. (If the bell and Gomco are not in the same package, another package may need to be opened by an assistant and handed to you in a sterile manner.)
- 7. Use the two still-attached edge hemostats to reapproximate the foreskin around the outside of the bell while applying gentle downward pressure on the bell's stem. Make sure that both mucosal and skin layers of the foreskin are reapproximated. The bell should occupy the space between the glans and the foreskin and sit against the coronal edge.
- 8. Once the Gomco bell is appropriately placed, grasp both sides of the dorsal slit near the middle of the incision with the tips

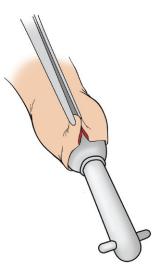

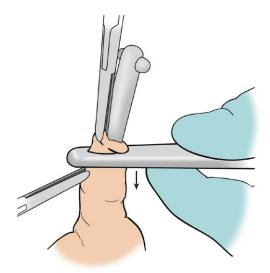

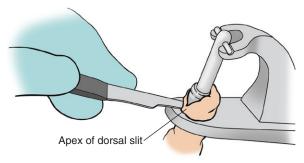

Figure 181-8 Reapproximate the dorsal slit around the Gomco bell.

of a third hemostat. This reapproximates the foreskin around the stem (Fig. 181-8). The approach with the hemostat is from above at a low angle, with handles up near the infant's umbilicus. This will ease the next step. (Some clinicians use a safety pin to hold the dorsal slit edges together in this step, but this unnecessarily increases the risk of a puncture injury to the clinician.)

- 9. Remove the two foreskin edge hemostats.
- 10. Place the end of the stem through the hole in the Gomco baseplate as far as it will go without dislodging the foreskin.
- 11. Reaching through the baseplate hole with a hemostat, grasp across the foreskin's dorsal slit just above the tips of the lower hemostat (Fig. 181-9). Remove the lower hemostat. Pull the stem and surrounding foreskin fully up through the baseplate hole. (If using a safety pin, pull the entire pin along with the bell through the baseplate hole. The safety pin will need to be turned parallel to the stem of the bell to pull it through the hole. The safety pin can then remain in place throughout the remainder of the procedure to avoid exposing its sharp tip.)
- 12. Assemble the Gomco clamp by grasping the wings of the bell's stem in the rocker arm's end, placing the rocker arm in its fulcrum slot, and loosely placing the nut on its screw.

**Figure 181-9** Bring the bell's stem and foreskin through the ring by exchanging hemostats.

**Figure 181-10** Excise the foreskin. The apex of the dorsal slit should be visible above the baseplate.

- 13. Make sure that the foreskin has been drawn through the hole in the Gomco clamp evenly from all sides. The apex of the dorsal slit must be above the baseplate. Using a hemostat or forceps, pull on the mucosal edge of the dorsal slit to be sure that the mucosal apex of the dorsal slit is also above the baseplate. Prior marking of the coronal edge position on the foreskin with a skin marker can be helpful at this point. When you are sure that the foreskin is evenly pulled through the Gomco clamp and the apex of the dorsal slit is visible above the baseplate, firmly tighten the clamp.
- 14. On the top side of the baseplate, the scalpel can be used to immediately excise the foreskin. It should be excised circumferentially and completely, on the top side, at the junction of the baseplate and the bell (Fig. 181-10). The top side of the baseplate is on the same side as the stem of the bell. Make sure that all skin and mucosal layers are removed. Any remaining tissue above the clamp will become necrotic and a possible source of infection. The excised ring of foreskin should be removed from the bell (it may be slid over the stem or cut away from the stem with scissors) and discarded in a biohazard waste container. Alternatively, the excised foreskin may be left on the stem until the device is disassembled.
- 15. Loosen and disassemble the Gomco clamp. There is no medical rationale for leaving the clamp on for any specific length of time
- 16. To remove the adherent foreskin edge from the bell, gently tease it away using a piece of gauze (Fig. 181-11).

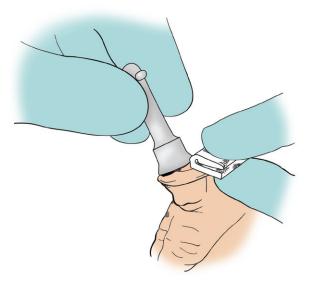

Figure 181-11 Tease the adherent tissue off the bell edge with gauze.

17. Follow steps 15 through 18 of the Mogen Technique section to check hemostasis, dress the wound, and document the procedure.

NOTE: A rare complication of using a Gomco clamp that is too large, or from pulling too much foreskin through the baseplate hole, is degloving of the penile shaft skin. In this situation, after the clamp and bell are removed, the shaft skin will retract too far and expose the underlying tissue proximal to the coronal sulcus. Attempts to control bleeding in the usual manner often fail. If bleeding is not controlled, a primary closure with four absorbable (5-0 chromic) sutures should be made. Sutures are placed circumferentially to reposition the retracted shaft skin to a point just proximal to the corona. Care must be taken in the ventral area to avoid the urethra. Some clinicians catheterize the infant with a 5-Fr feeding tube before performing the repair. Otherwise, no special aftercare is needed. If bleeding is controlled, degloving does not need to be repaired.

#### **Plastibell Technique**

- Choose an appropriate-size Plastibell, which is 1.3 cm for most normal newborns. (The Plastibell should fit like an appropriatesize Gomco bell.) Drop the device into the sterile field.
- 2. As in steps 1 through 5 of the Mogen Technique section, inspect the penis for abnormalities, consider marking the foreskin at the coronal edge, administer a penile subcutaneous ring block, position the infant (restrain if necessary), apply antiseptic, drape, and free the foreskin from the glans.
- 3. As in steps 3 through 5 of the Gomco Technique section, place a dorsal crushing clamp and remove it, cut a dorsal slit, and retract and fully free the foreskin. Leave the two foreskin edge hemostats in place.
- 4. Place the Plastibell string loosely around the base of the penis and put two twists in the string to start a surgeon's knot.
- 5. Place the Plastibell over the glans (Fig. 181-12) with its "wishbone" vertical (along the 12 to 6 o'clock axis). The edge of the Plastibell should just touch the coronal edge. Exchange the Plastibell for one of an appropriate size if this is not the case. It is particularly dangerous to use too large a Plastibell because the glans can push through its center and cause a paraphimosis, with resultant necrosis of the glans. If the size is correct, pull the foreskin over the device by manipulating the two grasping hemostats.
- 6. Once the Plastibell is appropriately placed, use a third hemostat to grasp both sides of the dorsal slit with the hemostat tips at about the middle of the incision. This will reapproximate the foreskin around the device and hold it in place (Fig. 181-13).

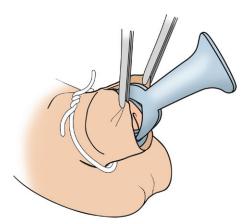

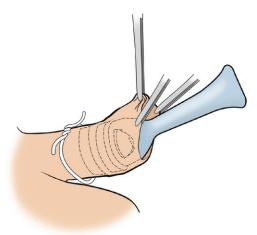

Figure 181-12 Place the Plastibell on the glans and check for proper size.

**Figure 181-13** Reapproximate the foreskin around the Plastibell and hold it in place with a hemostat.

- 7. Ensure that the string groove of the Plastibell is below the apex of the dorsal slit and at the appropriate place on the foreskin. Adjust the grasping hemostat if necessary. When certain of Plastibell placement, remove the two foreskin edge hemostats.
- 8. Place the string over the groove in the Plastibell and tighten the string just until it remains in place.
- 9. Check the placement of the string and bell again, making sure that the apex of the foreskin incision is distal to the string. Be sure that you are not removing too much foreskin and that the Plastibell can move freely on the glans.
- 10. Tighten the string as much as possible and hold at this tension for a few seconds. Complete the surgeon's knot in the string and trim the excess string to ¼ inch in length (Fig. 181-14).
- 11. Remove the hemostat that has been approximating the dorsal slit.
- 12. Using iris scissors, cut the foreskin away to within 3 mm of the string. Be careful not to cut the string (Fig. 181-15). Discard the foreskin in a biohazard waste container.
- 13. Holding the body of the Plastibell between the index finger and thumb of one hand, bend the wishbone with the other hand until it snaps at its junction with the bell (Fig. 181-16).
- 14. Verify again that the Plastibell can move up and down on the glans and that the meatus is not occluded.
- 15. As in steps 15 through 18 of the Mogen Technique section, check for bleeding, cover with white petrolatum, reapply the diaper, and record the procedure in the chart.

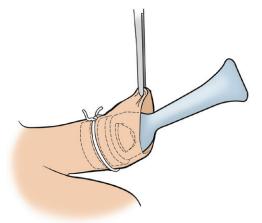

Figure 181-14 String in the groove of the Plastibell with knot trimmed.

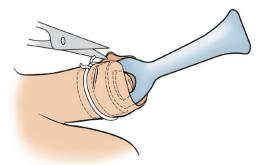

Figure 181-15 Trim the excess foreskin with iris scissors.

### Postprocedure Management and Parent Education

#### All Techniques

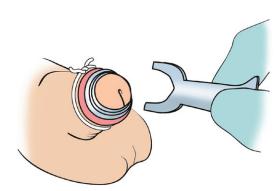

Parents should report any bleeding or signs of infection. It is normal to have a red, angry-looking glans, often with a yellowish crust that may last for a week. Acetaminophen (10 to 15 mg/kg every 6 to 8 hours) is given for any apparent pain or irritability. Rarely is any analgesic needed beyond 24 hours. The patient education handout includes postprocedure instructions for parents. (See the sample handout titled "Newborn Circumcision" available online at www. expertconsult.com.)

After a Mogen or Gomco procedure, parents are told to retract the penile shaft skin back from the corona and to apply white petrolatum to the area at each diaper change. After the Plastibell falls off, this same procedure is followed. This should continue for a week to prevent adhesions from forming. To prevent the glans from sticking to the diaper, parents should apply a smear of white petrolatum to the front of the diaper for the first week. They can wash the penis with soap and water the day after surgery.

Parents are instructed to watch for meatal stenosis. Meatal stenosis appears as a pinhole urethra causing a narrow or angulated urinary stream. This can be associated with enuresis or incontinence. Meatotomy is a simple office procedure and will usually correct the problem.

#### Plastibell Technique

In addition to following all of the same basic instructions for patients who undergo circumcision using the Mogen or Gomco clamp, parents need to know what to expect with a Plastibell. They should know that the foreskin remaining beyond the string will turn black and necrotic and fall off along with the Plastibell within 1 week. Each Plastibell device comes with a postoperative education card that is given to the parents.

**Figure 181-16** Snap the Plastibell at the junction of the ring and the wishbone.

#### **Complications**

- Bleeding.
- Infection (most common with Plastibell because of the retained tissue and the presence of a foreign body).
- Trauma to the glans or urethra.
- Poor cosmetic result due to remaining adherence of mucosa to glans, removal of too much or too little foreskin, or uneven removal of foreskin. Most cosmetic problems resolve as the infant grows and the wound heals. Secondary intervention is very infrequently necessary.
- Paraphimosis from inadequate opening of the Mogen crush line after the procedure is completed or from the use of Plastibell that is too large. A Plastibell may be removed with orthopedic bonecutting forceps.
- Degloving of penile shaft skin (Gomco only; see the Gomco Technique section).
- Meatal stenosis: rare, but a possible late complication.

#### **MEATOTOMY (NEWBORN AND OFFICE)**

#### **Indications**

- Newborn (following circumcision): width of meatus less than 2 mm or less than 25% to 30% of diameter of glans
- Male infant younger than 1 year of age: symptoms of meatal stenosis and unable to easily insert 5-Fr feeding tube
- Male child older than 1 year and younger than 6 years of age: symptoms of meatal stenosis and unable to easily insert 8-Fr feeding tube

#### **Contraindications**

The contraindications are the same as for circumcision, except the child can be older than newborn for office meatotomy.

#### **Preprocedure Patient Preparation**

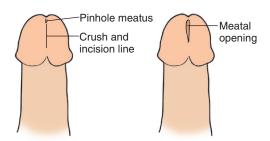

If there is a possibility that newborn meatotomy may be performed, the procedure, its alternatives, and its risks and benefits should be explained. Meatotomy is often added to the informed consent for circumcision. If office meatotomy is to be performed in an older male child, similar explanations should be made and informed consent obtained.

#### **Equipment**

- Antiseptic solution (e.g., povidone-iodine, chlorhexidine)
- Antibiotic ointment
- Fenestrated drape
- Straight mosquito hemostat
- Straight iris scissors
- Lidocaine–prilocaine cream or gauze soaked with 2% lidocaine (office meatotomy)
- 30-gauge needle with 1-mL syringe and 1% lidocaine without epinephrine (office meatotomy, alternative for anesthesia)

#### **Technique**

 Anesthesia is usually already adequate for a newborn having just undergone circumcision. For office meatotomy, lidocaine-prilocaine cream should be smeared liberally over the entire glans, especially the ventral portion and the meatal opening. It should be secured in place with occlusive dressing and left for at least an hour of contact time before the procedure. Alternatively, a

**Figure 181-17 A,** Meatal stenosis and location of crush line. **B,** Meatus after meatotomy.

small amount of lidocaine can be injected directly into the meatal skin. For very anxious children (for 2 of 58 children in one study, ages 30 months to 10 years, a preoperative anxiolytic was used), it may be useful to use pediatric sedation (see Chapter 7, Pediatric Sedation and Analgesia).

- Apply antiseptic solution to the penis and place a fenestrated drape.
- 3. Place one tip of the straight mosquito hemostat, lubricated with antiseptic solution, inside the meatus at the 6 o'clock position. The tip should be several millimeters inside the meatus, the distance being judged by the severity of stenosis and patient age. In the newborn, the other tip should be no farther than the frenulum.
- 4. Close the hemostat to obtain a crush line of hemostasis on the inferior side of the meatus. Frequently the majority of the crush line will be located on the thin, sometimes translucent, inflammatory membrane that has caused the meatal obstruction.
- Using the fine iris scissors, cut through the center of the crush line (Fig. 181-17). Be careful to cut only in the crush line; if you extend laterally or past the crush line, bleeding may occur.
- A closed hemostat can then be inserted into the urethra to gently and blindly palpate for distal urethral webs. If webs are noted, urologic referral is indicated.
- A small amount of antibiotic ointment is then placed on the incision.

## Postprocedure Management and Parent Education

The meatotomy site should be shown to parents, and they can then be given instructions for care. Parents are instructed to insert a small dilator into the meatus daily for 2 weeks to prevent recurrence of the stenosis. Use either a small eyedropper or the tip of a tube of ophthalmic antibiotic ointment as the dilator. White petrolatum ointment can be used as a lubricant.

#### **SAMPLE OPERATIVE REPORT**

After most neonatal circumcisions (or meatotomies) in the United States, only a cursory operative note is made in the chart—for example, "1% lido ring block, Mogen circ without complication, infant tolerated well, parents given instructions for care." This chart is signed by the clinician, and the date and time are noted.

# PEDIATRIC ARTERIAL PUNCTURE AND VENOUS MINICUTDOWN

John J. Andazola • Karyn B. Kolman

#### **ARTERIAL PUNCTURE**

Arterial blood may be needed for blood gas analysis or for routine laboratory analysis. In the infant or child, the radial artery is the most appropriate and most commonly selected site for arterial puncture. The posterior tibial and dorsalis pedis arteries are optional sites, but each has its own risk of complications. Because of the risk of thrombosis, use of the femoral artery for arterial puncture in the infant or child should be reserved for emergencies. Likewise, because of the risk of median nerve damage and the fact that the brachial artery has minimal collateral circulation, the brachial artery should be reserved as a last resort in emergencies. The temporal artery should probably not be used because of the high risk of neurologic complications.

The radial artery is located just medial to the styloid process of the radius. It is palpable between the radius and the tendon of the flexor carpi radialis (see Chapter 208, Arterial Puncture and Percutaneous Arterial Line Placement).

#### **Indications**

- To obtain arterial blood from the pediatric patient in respiratory distress or for other studies that require arterial blood
- To guide the management of the pediatric patient receiving ventilatory support or undergoing intensive respiratory therapy (e.g., to confirm hypoxia or hypercapnia when pulse oxymetry [SaO<sub>2</sub>] or end-tidal CO<sub>2</sub> [ETCO<sub>2</sub>] monitoring, respectively, indicates it)
- To obtain blood for routine laboratory analysis when venous blood cannot be obtained

**NOTE:** The last indication is controversial. The benefit must outweigh the higher risk of obtaining an arterial sample.

#### **Contraindications**

Infection, burns, local skin damage, trauma, or severely disturbed anatomy at the site of the intended puncture are all contraindications. They are considered *relative* contraindications in a lifethreatening situation.

#### **Equipment and Supplies**

- Commercially available heparinized arterial blood gas (ABG) syringe or 1-mL (tuberculin syringe) to 3-mL syringe (to be flushed with heparin)
- Rubber stopper or syringe plug to seal blood sample
- 23- to 27-gauge butterfly scalp vein needle or standard 23- to 27-gauge needle (the smaller the needle, the lower the risk of complications)

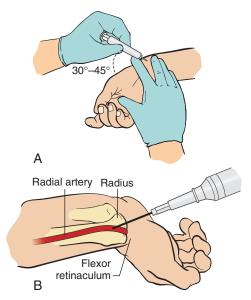

- Antiseptic skin preparation, such as povidone—iodine or chlorhexidine, and 70% isopropyl alcohol
- Container of crushed ice for sample transport
- Sterile 4 × 4 gauze pads
- Sterile gloves
- Goggles or eye protection
- Bright light source (e.g., bright penlight, otoscope) for transillumination (optional)
- 1 or 2 mL heparin, 1000 U/mL (optional, for use in nonheparinized syringe)
- In the alert patient (optional), 1% or 2% lidocaine without epinephrine and a 1- or 3-mL syringe with 25- or 27-gauge, %-inch (1.6-cm) needle
- Arm or leg board (optional)

#### **Precautions**

The modified Allen test is performed to ensure patency of the ulnar artery before an arterial puncture or the placement of an indwelling arterial catheter. Verifying adequate collateral circulation may reduce the risk of ischemic complications if thrombosis of the radial artery occurs. (See Chapter 208, Arterial Puncture and Percutaneous Arterial Line Placement, for a description of the modified Allen test as well as other techniques available to test for collateral circulation.)

#### **Technique**

- Always perform a modified Allen test (or equivalent) to confirm adequate collateral circulation.
- 2. Attach a butterfly needle (preferred for infants and neonates) or a standard 23- to 27-gauge needle to a heparinized ABG syringe. Alternatively, draw a small amount of heparin into the syringe and eject the heparin. The heparin remaining in the syringe will prevent the sample from clotting as well as decrease the dead space in the syringe. Heparin has a very low pH, so avoid using excessive heparin, which could result in falsely abnormal ABG results. If the sample will be used for another laboratory test, do not use heparin.
- 3. Immobilize the upper extremity by taping it to an arm board or by having an assistant manually stabilize it.
- 4. Grasp the wrist with the nondominant hand and identify the radial artery by dorsiflexing and slightly externally rotating the wrist and palpating over the distal volar (palmar) radius. Using a bright light source for transillumination may help locate the artery, especially in newborns. Cleanse the site of intended puncture with an antiseptic solution, which can be wiped off with alcohol swab. If the patient is alert, the area can also be infiltrated with 1% to 2% lidocaine without epinephrine.
- Universal blood and body fluid precautions should be followed. Insert the needle with the bevel up, at the point of maximum

**Figure 182-1** Pediatric arterial puncture. **A,** Anatomic location of the radial artery with immobilization of the wrist in hyperextension. **B,** The artery is entered with the bevel up and the needle at 30 to 45 degrees from horizontal.

pulsation, at a 30- to 45-degree angle (Fig. 182-1) to the distal skin. Usually little aspiration is needed to fill the syringe when the artery is pierced. If the syringe does not flash blood immediately, continuous gentle suction can be applied with the plunger of the syringe as the needle is removed or on the next attempt. Be aware that arterial blood may not flash into the syringe as vigorously in a child as in the adult patient. If using the butterfly needle, have an assistant maintain gentle suction while the needle is advanced.

- 6. If resistance is encountered, most likely the needle has made contact with underlying bone (radius). At this point, withdraw the needle very slowly while maintaining gentle suction on the plunger until there is blood return. If there is no blood return and the tip of the needle has been withdrawn to a point just beneath the skin, readvance the needle toward the point of maximal pulsation before withdrawing it from the skin. Although the risk of complications increases with the number of attempts, several attempts can be made in this manner causing minimal trauma to the infant before choosing another site.
- 7. When arterial blood is encountered, withdraw 0.3 to 0.5 mL into the syringe before removing the needle. Leave the butterfly needle in place (with its extension tubing) if more blood is needed for other analyses. This will facilitate changing the syringe. For blood gas analysis, remove any bubbles from the syringe and then seal it. Place it on ice and immediately transport to the laboratory.

**NOTE:** The total blood volume in a neonate is usually about 80 mL/kg, and the volume of blood withdrawn should not exceed 3% to 5% of this total blood volume. As an example, 8 mL is 5% of the total blood volume in a 2-kg infant.

8. After removing the needle, always maintain manual compression at the arterial puncture site for a minimum of 5 minutes to prevent the formation of a hematoma. Apply firm, but not occlusive pressure.

#### **Sample Operative Report**

See the sample operative report online at www.expertconsult.com.

#### **Complications**

- Bleeding and hematoma formation (to minimize this risk, use the smallest needle possible)
- Arterial spasm, thrombosis, and embolism (risk increases with repeated punctures in the same location; however, arterial spasm will usually resolve spontaneously, and the artery will usually recanalize over time after thrombosis)
- Nerve injury
- Infection
- Spurious laboratory results (see Chapter 208, Arterial Puncture and Percutaneous Arterial Line Placement, for a discussion)

**NOTE:** Because the radial artery is not close to a nerve or vein, its puncture usually results in fewer complications than puncture of the posterior tibial or dorsalis pedis artery. Repeated puncture at the same site increases the chance of complications but may be unavoidable.

#### **Interpretation of Results**

See Table 182-1.

#### VENOUS MINICUTDOWN

Obtaining percutaneous venous access in infants or in hypovolemic children can be a challenge. In an emergent situation, when percutaneous venous access in not easily obtainable, intraosseous line placement is the preferred alternative (see Chapter 198, Intraosseous Vascular Access). If intraosseous line placement is not possible, venous cutdown can be used to gain vascular access. Venous cutdown can often be performed rapidly, usually in a matter of minutes. Chapter 209, Venous Cutdown, offers technical advice on the overall mechanics of venous cutdown. This chapter offers an abbreviated and clinically easier method for pediatric patients in emergencies: the minicutdown. Although standard venous cutdown takes 5 to 15 minutes, even in the hands of a skilled clinician, minicutdown is less complicated and can usually be performed in less than 5 minutes.

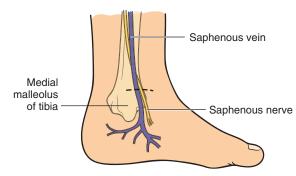

The saphenous vein is a consistent anatomic structure and is located a fingerbreadth (1 cm) anterior to and a fingerbreadth (1 cm) superior to the medial malleolus at the ankle in infants and 2 cm anterior and superior in older children (Fig. 182-2). Because of its superficial and consistent location, the saphenous vein is the most common site for cutdown in the pediatric patient. The saphenous nerve travels with the saphenous vein and is often transected when isolating the saphenous vein at the ankle, but fortunately it is of minimal clinical significance. In this location, there is very little subcutaneous tissue, and other than the saphenous vein and nerve, there are few other structures between the dermis and the tibial periosteum.

#### **Indications**

In an emergency, the inability to obtain needed percutaneous intravenous (IV) or intraosseous vascular access in a matter of minutes

TABLE 182-1 Normal Values for Arterial Blood Gases Based on Age

Age	рН	PaO <sub>2</sub> (mm Hg)	Paco₂ (mm Hg)	HCO <sub>3</sub> (mEq/L)
Birth Birth–I yr I–2 yr 7–19 yr >19 yr	7.26–7.29	60	55	19
	7.37	70	33	20
	7.40	90	34	20
	7.39	96	37	22
	7.35–7.45	90–110	35–45	22–26

**Figure 182-2** Path of the saphenous vein as it courses anterior to the medial malleolus of the tibia. An incision (about 1 to 2 cm in length) through the skin is made perpendicular to the long axis of the tibia. (Redrawn and modified from Bailey P: Vascular access for pediatric resuscitation and other pediatric emergencies. In Rose BD [ed]: UpToDate. Waltham, Mass, UpToDate, 2007.)

or the inability to maintain a peripheral IV line indicates the need venous minicutdown.

#### **Contraindications**

- Vascular injury or long bone fracture proximal to the site of the intended cutdown (proximal venous flow or vascular access may be obstructed, so this is a relative contraindication because the minicutdown may not work)
- Infection, burn, trauma, or severely disturbed anatomy at the site
  of the intended cutdown (relative contraindication in life-threatening
  situation)
- Anticoagulation from bleeding disorders or anticoagulant therapy (relative contraindication in life-threatening situation)

#### **Equipment and Supplies**

- Mounted no. 15 blade scalpel
- Mosquito hemostat
- Antiseptic skin preparation, such as povidone—iodine or chlorhexidine, and 70% isopropyl alcohol
- 4-0 silk suture, 4-0 nylon skin suture
- Sterile 4 × 4 gauze pads
- Sterile gloves
- Goggles or eye protection
- 16- to 20-gauge standard over-the-needle IV catheter
- Skin retractors (optional)
- Leg board (optional)
- In the alert patient (optional), 1% or 2% lidocaine without epinephrine and a 1- or 3-mL syringe with 25- or 27-gauge, ½-inch (1.6-cm) needle

#### **Technique**

- Immobilize the lower extremity by securing it to a board or by having an assistant manually hold the patient. The lower extremity should be extended and slightly externally rotated.
- Cleanse this area with an antiseptic solution. If time allows, wipe the antiseptic solution off with an alcohol pad. Follow universal blood and body fluid precautions. If time allows and the patient is alert, anesthetize the area with lidocaine.
- 3. Locate the medial malleolus, and at the appropriate location anterior (one to two fingerbreadths [1 to 2 cm], depending on age) and superior (1 to 2 cm, depending on age) to it, make a 1- to 2-cm transverse (perpendicular to the vein and the tibia) incision through the dermis, exposing the underlying subcutaneous tissue. (In other words, the incision should be made in the anteroposterior direction.)

NOTE: The incision should be very superficial, limited to the skin and only exposing the subcutaneous tissue. Incising into the subcutaneous tissue may result in transection of the vein with subsequent bleeding into the surgical field, obscuring the vein.

4. Exposure of the vein is accomplished with traction on either side of the incision with the nondominant hand (or skin retractors) and blunt dissection with a mosquito hemostat. Most clinicians insert the hemostat with the tips down against the posterior tibia, down to the periosteum, and aim it in the direction of the incision (transverse to the vein). The tips are then advanced across the tibia, with downward pressure so that they slide across the periosteum, until they reach the anterior border of the tibia (the tips will slide beneath the saphenous vein). The tips are then rotated 180 degrees (until they are facing upward), and all of the tissue between the skin and the tibial periosteum should be on top of the hemostat. When the hemostat is opened widely, the saphenous vein should be visualized in this tissue (usually a scant amount of subcutaneous tissue). Frequently, in older children, the saphenous nerve can also be visualized and avoided.

Alternatively, the clinician can attempt to visualize the vein by bluntly spreading the subcutaneous tissue with the hemostat tips, staying parallel to the course of the vein (perpendicular to the incision; Fig. 182-3A). However, some experts consider this technique to take longer because it may be difficult to find the vein against the white background of the periosteum.

With either technique, if there is difficulty visualizing the vein, the foot can be squeezed to backfill the vein. This should improve localization of the vein.

- 5. When the saphenous vein is identified, pass a 4-0 silk suture beneath the vessel and clamp both ends of the suture with a hemostat (Fig. 182-3B).
- 6. Using upward traction on the vein with the suture to stabilize it, cannulate the vessel with an IV catheter under direct visualization (Fig. 182-3C). Advance the catheter in the usual fashion, then attach IV tubing and begin infusing fluid. As with percutaneous line placement, steady fluid flow indicates successful cannulation.
- 7. Suture the catheter in place. (With the minicutdown technique, the vein is not ligated after cannulation.)
- The incision site is then sutured with nylon suture and a sterile occlusive dressing applied. Because the minicutdown technique does not destroy the vein, standard cutdown can still be performed if needed.

#### **Sample Operative Report**

See the sample operative report online at www.expertconsult.com.

#### Complications

- Wound infection
- Local hematoma
- Phlebitis
- Sensory nerve damage
- Damage to adjacent structures from incision and dissection

**NOTE:** Because this is only a temporary procedure, the risk of these complications is minimal.

#### **Postprocedure Management**

A sterile occlusive dressing should be placed immediately and routine wound care provided. Once other means of vascular access are obtained, the venous minicutdown catheter should be removed and the incision repaired with appropriate suture material.

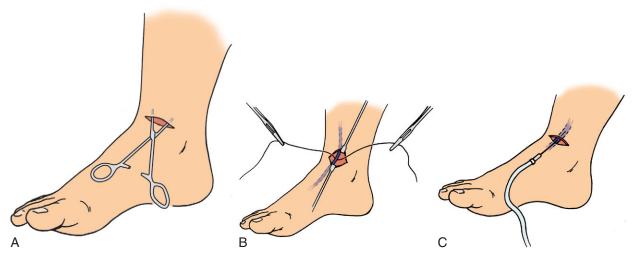

Figure 182-3 Venous minicutdown. A, Blunt dissection after making a transverse incision. B, Localization of the vein. C, Cannulating the vein.

# PEDIATRIC SUPRAPUBIC BLADDER ASPIRATION

Carlos A. Moreno

Suprapubic bladder aspiration is a method of obtaining a sterile urine specimen in a young infant when other methods are unsatisfactory. This procedure is most successful in an infant younger than 2 years of age because at that age the bladder is an abdominal organ. After 2 years, as the child grows, the bladder moves into the pelvis, increasing both the difficulty of the procedure and the risk of complications. (See Chapter 225, Emergency Department, Hospitalist, and Office Ultrasonography [Clinical Ultrasonography], for a method of confirming a full bladder and determining where to direct the needle.)

#### **INDICATIONS**

- To obtain sterile urine for culture in an infant or child younger than 2 years of age (e.g., suspected urinary tract infection [UTI] or sepsis)
- To decompress the urinary bladder when there is urethral obstruction (after decompression, a referral should be made to pediatric urology)

#### **CONTRAINDICATIONS**

#### **Absolute**

There are no absolute contraindications.

**NOTE:** Some experts now consider "blind" aspiration to be an absolute contraindication. They suggest that the bladder location should be confirmed by palpation, percussion, or transillumination or visualized with ultrasonography.

#### **Relative**

- Bleeding abnormality or coagulopathy
- Infection or loss of integrity of skin or fascia at the site of needle insertion (e.g., burn, cellulitis)
- Anatomic genitourinary tract anomalies
- Bowel distention (e.g., ileus, obstruction)
- Scars from previous lower abdominal surgery that might cause adhesions

**NOTE:** With ultrasonography-directed aspiration, the last three contraindications may be overcome (see Chapter 225, Emergency Department, Hospitalist, and Office Ultrasonography [Clinical Ultrasonography]).

#### **EQUIPMENT AND SUPPLIES**

- Povidone-iodine solution
- 70% isopropyl alcohol
- Sterile 4 × 4 gauze pads

- Sterile gloves
- 3-mL sterile syringe with 1- or 1½-inch, 22- or 23-gauge needle
- Sterile urine specimen container
- Adhesive bandage
- 1% lidocaine in a tuberculin syringe with ½-inch, 27-gauge needle (optional)
- High-frequency ultrasound (5- to 10-MHz) probe and acoustic gel (optional)

#### PREPROCEDURE PATIENT PREPARATION

The parent(s) should be informed about the indication(s) for suprapubic aspiration, as well as alternatives and possible complications. In nonemergent situations, informed consent should be obtained. The parent(s) should be given the option to leave the room or to look away as the procedure is being performed because it can be disconcerting to some parents.

#### **PROCEDURE**

- Before bladder aspiration, the infant's diaper should be dry and urination should not have occurred within the previous hour. Often the full bladder can be palpated, percussed, or transilluminated to ensure a full bladder. An alternative is to perform a quick ultrasonographic examination to confirm a full bladder.
- 2. Hold the infant in the supine, frog-leg position. Observe universal blood and body fluid precautions.
- Urination can be prevented by gently pinching the penis or by applying manual pressure in the area of the anterior rectum or urethral meatus in a female infant.
- 4. Cleanse the lower abdomen with povidone–iodine and then remove the iodine with 70% isopropyl alcohol.
  - **NOTE:** At this point, some clinicians inject a small amount (<1 mL) of a local anesthetic, such as 1% lidocaine, to raise a subcutaneous wheal in the area of the intended puncture site. However, this is considered optional by many clinicians because the discomfort caused by the lidocaine is similar to that caused by the puncture for bladder aspiration.
- 5. With the needle attached to a 3-mL sterile syringe, direct the needle into the midline of the abdomen at a point 1 cm above the symphysis pubis (there is usually a transverse suprapubic crease at this location). Hold the needle perpendicular to the abdomen or direct it slightly caudal (Fig. 183-1).
- 6. Aspirate gently with the syringe while advancing the needle. To avoid puncturing the posterior bladder wall or retroperitoneal structures, do not advance the needle after urine begins to enter the syringe. If the bladder is full, urine is usually obtained before the needle is inserted to its full depth.

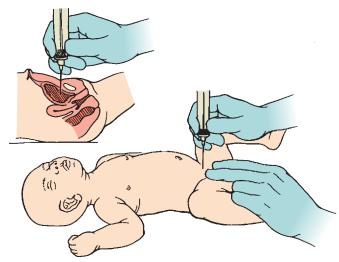

Figure 183-1 Proper technique for suprapubic bladder aspiration.

7. If no urine is obtained, withdraw the needle without removing it from the skin and attempt bladder puncture again, angling 20 degrees more caudal. If three attempts are unsuccessful, the bladder is considered empty. The procedure can be repeated in an hour if the patient is stable. Some urine should have accumulated over this time.

**NOTE:** An alternative is to catheterize the infant, especially if he or she is too unstable to wait an hour. If ultrasonography is available, it can be helpful to confirm the presence of urine before subjecting the infant to catheterization and risk of iatrogenic LITI

- 8. After withdrawing the needle, immediately apply pressure to the puncture site until it can be covered with a sterile gauze dressing. Next, apply mild pressure to the dressing for a minute. After a minute, if there is adequate hemostasis and no urine draining from the puncture site, pressure can be discontinued and the bandage applied.
- 9. Transfer the aspirated urine to a sterile container and transport to the laboratory for analysis, culture, and sensitivity.

#### **COMPLICATIONS**

- Microscopic hematuria (typically transient, resolving without specific treatment)
- Iatrogenic UTI (risk is minimized by the use of sterile technique)
- Perforation of the bowel (rare and may be managed by close observation and, if necessary, antibiotic administration)
- Retroperitoneal hematoma or damage to retroperitoneal structures (very rare)
- · Infection of the abdominal wall

#### POSTPROCEDURE PATIENT EDUCATION

The parent(s) should be given instructions to keep the site clean and to seek medical care for fever, nausea, vomiting, or infection at the puncture site.

## Umbilical Vessel Catheterization

Carman H. Whiting

Being able to quickly assess and rapidly intervene in a severely ill infant is essential. Because the umbilical vessels are easily visualized, they are an excellent route for catheterization to provide central vascular access. Whereas umbilical artery catheterization allows for accurate monitoring of central arterial pressure directly through the aorta, umbilical vein catheterization allows for central venous pressure (CVP) monitoring through the inferior vena cava. Umbilical vein catheterization also provides access for rapid infusion of lifesustaining therapies (Fig. 184-1).

Primary care clinicians may need to perform umbilical vessel catheterization in the delivery room for a newborn resuscitation or in the emergency department for a newborn or infant in distress. They may also need to perform it in the nursery or neonatal intensive care unit (NICU) for an infant requiring continuous monitoring or frequent infusions of medications or fluids. In fact, both vessels are frequently catheterized in the NICU for premature infants requiring prolonged vascular access or monitoring.

Compared with the vein, the umbilical artery is a more durable vessel with higher-velocity blood flow; therefore it is easier to visualize and there is a slightly lower risk of complications when it is catheterized. Inserting an umbilical artery catheter (UAC) or an umbilical vein catheter (UVC) is easier if performed in the first 30 to 60 minutes of the infant's life. However, a UAC may be inserted up to the 7th day of life and a UVC at up to 2 weeks of age. Despite the fact that the vessels are easily accessible, placing a UAC can be a time-consuming procedure and requires skill and experience. Contraindications or difficulty obtaining a UAC insertion may necessitate the need for a UVC for infusions because a UVC insertion is easier to perform. A UVC is also an option if peripheral intravenous access is difficult to obtain, which is likely the case in very premature infants. After the first day of life, there are few data supporting any benefit of a UAC over a UVC for infusion, although an attempt should always be made to obtain peripheral venous access before either of these is inserted, except in infants of very low birth weight.

#### **INDICATIONS**

#### **Umbilical Artery Catheterization**

- Newborn resuscitation requiring monitoring for cardiorespiratory distress (e.g., arterial pressure monitoring, frequent arterial sampling)
- Newborn or infant in a NICU requiring
  - Mechanical ventilation for respiratory distress (i.e., frequent arterial sampling)
  - Oxygen hood and greater than 40% oxygen (FiO<sub>2</sub> >0.4) requirement with an abnormal chest radiograph (i.e., frequent arterial sampling)

 Exchange transfusion that can be performed through a UAC (e.g., newborn weighing <1800 g)</li>

#### **Umbilical Vein Catheterization**

- Newborn resuscitation requiring
  - Administration of drugs, blood, blood expanders, or fluids
  - Monitoring for possible cardiorespiratory distress (e.g., CVP monitoring)
- Newborn or infant in the NICU requiring
  - Greater than 12.5% dextrose to maintain blood glucose while taking nothing by mouth (NPO)
  - Pressor drips, total parenteral nutrition (TPN) solution, or hypertonic medications (e.g., newborn weighing <1000 g or who is critically ill)
  - Exchange transfusion or partial exchange transfusions that can be performed through a UVC (e.g., newborn weighing <1800 g)</li>

**NOTE:** By convention, a newborn is defined as an infant younger than 1 month of age.

#### **CONTRAINDICATIONS**

- There are no contraindications during the first hours of life if the newborn has normal anatomy and no local skin infections.
- Vascular insufficiency of a lower extremity is a contraindication to UAC.
- Local infection (e.g., omphalitis, impetigo) and abdominal distention (possibly caused by intestinal hypoperfusion or necrotizing enterocolitis) are contraindications that can develop after the first few hours of life.

#### **EQUIPMENT**

- Sterile measuring tape
- 3.5- to 5.0-Fr umbilical catheter for UAC; up to 8-Fr umbilical catheter for UVC
- Surgical cap and mask; sterile gown and gloves
- Eye protection for clinician
- Povidone–iodine or antiseptic scrub solution
- Three-way stopcock (sterile); locking connectors
- Heparin for flush (1 to 2 U heparin/mL of 0.25 normal saline [NS])
- Sterile instrument tray with small hemostats, forceps (iris curved), scissors, needle holder, straight forceps, mounted no. 11 scalpel blade, and drapes
- Antibiotic ointment
- 4-0 or 5-0 silk suture with a small needle or a catheter stabilizer

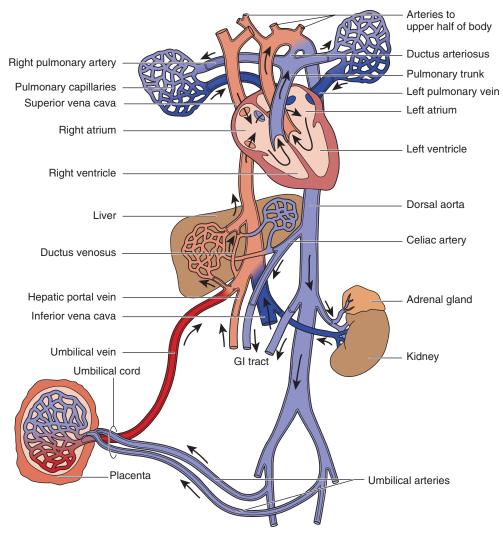

Figure 184-1 Fetal circulation at term. (Modified from Carlson B: Human Embryology and Developmental Biology, 2nd ed. St. Louis, Mosby, 1999.)

- Sterile umbilical tape
- Infant radiant warmer, means of restraint, cardiac and oxygen saturation monitors, supplemental oxygen
- 5% or 10% dextrose in water or NS infusion setup (use heparin 1 U/mL, unless medications are to be administered that are incompatible with heparin) with fluid chamber, 0.22-µg filter, and infusion pump
- Adhesive tape

A rule of thumb for selecting UAC size is to use a 5-Fr catheter for infants weighing more than 2000 g and a 3.5- to 4-Fr catheter for infants weighing less. Because the lumen of the vein is larger, a 5- to 8-Fr catheter can be used for UVC in term infants (>1800 g), especially infants requiring exchange transfusion. The catheter may be composed of any U.S. Food and Drug Administration–approved material; double-lumen catheters are also available.

#### PREPROCEDURE PATIENT PREPARATION

The newborn needing umbilical catheterization typically demonstrates signs and symptoms of cardiorespiratory distress shortly, if not immediately, after birth. If performed as an emergency procedure, implied consent and the indications should be documented in the chart. Explain the need for the procedure to the parent(s) when there is time. For less urgent insertions, obtain informed consent

from the parent(s) after discussing the alternatives, risks, and potential benefits of the procedure.

#### **TECHNIQUE**

When the infant arrives at the nursery, if umbilical catheterization is probable, the umbilical stump should be left at least 4 cm long. The two thick-walled arteries and the single vein should be easily identifiable. Place the infant under an infant warmer and restrain, if possible. The cardiac rate should be monitored and adequate oxygenation should be provided throughout the procedure.

- 1. Set up the tubing, fluids, fluid chamber, 0.22-µg filter, and infusion pump. Flush and fill the tubing with heparin flush to remove air from the system.
- 2. Prepare the entire abdomen from xiphoid to pubis with sterile povidone—iodine or antiseptic scrub solution. Scrub the umbilical stump and apply sterile drapes. Observe universal blood and body fluid precautions when performing the procedure.
- Calculate the insertion length of the catheter for proper placement.
  - UAC. There are two commonly used, standard insertion depths for UAC. One results in "high" placement of the catheter tip, which is above the diaphragm at the level of the thoracic aorta (spinal level T6–T9). This site places the tip

between the ductus arteriosus and the origin of the celiac axis. The second site results in "low" placement of the catheter tip (spinal level L3–L5), which is below the diaphragm. This site places the tip between the inferior mesenteric artery and the bifurcation of the aorta.

For high placement: (a) measure the axial or longitudinal distance from the level of the umbilicus to the level of the shoulder or clavicle (shoulder–umbilicus length). Then use the nomogram shown in Figure 184-2A; or (b) calculate the length based on birth weight (BW): length (cm) = (3 × BW [kg]) + 9.

When a nomogram or the birth weight is not available or the situation is urgent, if the shoulder–umbilicus length is greater than 13 cm, simply add 1 cm to the shoulder–umbilicus length. This results in a reasonable estimate for the catheter insertion depth. When the shoulder–umbilicus length is less than 13 cm, insert the catheter 2 cm further than the shoulder–umbilicus length.

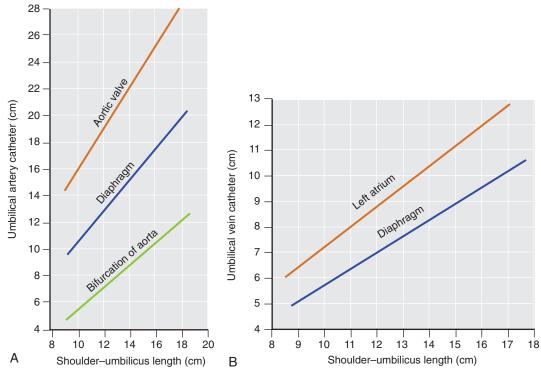

For low placement: (a) use the nomogram (see Fig. 184-2A) with the shoulder–umbilicus length, or (b) calculate the length based on birth weight: length (cm) = BW (kg) + 7.

If a nomogram or the birth weight is unavailable or the situation is urgent, insert the catheter until blood is first encountered and then advance it 1 additional centimeter.

**NOTE:** One meta-analysis study found that high-placement UACs (compared with low placement) have fewer acute vascular complications and no increase in permanent vascular sequelae.

• UVC. For CVP readings, place the catheter tip 0.5 to 1 cm above the diaphragm. The insertion depth can be estimated with a nomogram (Fig. 184-2B) or with one of two formulas: (a) length (cm) = shoulder–umbilicus length (cm) × 0.6, or (b) length (cm) = (UAC insertion length [cm] × 0.5) + 1. If

- a nomogram or the birth weight is not available or the situation is urgent, a second option is to insert the UVC gently for 4 to 5 cm until blood return is noted. Never insert the UVC more than 5 cm without radiographically checking the placement because the tip may be in the portal vein. If the catheter is being placed for a single-exchange transfusion, it may be inserted to just beneath the skin (3 to 5 cm), as long as good blood flow is noted and there is no leakage around the catheter.
- 4. Loosely tie the sterile umbilical tape around the proximal stump. It should be tight enough to control bleeding but loose enough to allow later passage of the catheter. A silk suture can be used as a pursestring ligation in the same manner.
- 5. Holding the cord with straight forceps, transect it with the scalpel approximately 1 cm above the umbilical tape (Fig. 184-3A). Correctly identify the arteries and the vein. Because the vein is the single vessel and has the largest lumen, it is usually the easiest to identify. It can then be distinguished from the thicker-walled arteries that are usually lateral to the vein.
- 6. The cord stump should be grasped with one or two hemostats (on opposite sides of the umbilicus) and the cut edge everted. Gently dilate the desired vessel with small curved forceps (Fig. 184-3B). To do so, insert one prong, then both prongs of the iris forceps, then open the forceps prongs slightly to dilate the lumen to a depth of about 1 cm. Next, grasp the catheter approximately 1 cm from the tip with your thumb and forefinger or with the forceps. Gently insert the catheter through the vessel lumen to the length previously measured (Fig. 184-3C).
- 7. Insertion
  - UAC. Placing traction on the cord stump in a cranial direction usually facilitates directing the catheter caudally. With insertion, use gentle, constant pressure to overcome any resistance. Resistance is usually encountered at a depth of about 1 to 2 cm as the vessel turns caudad. Slight resistance may again occur when the catheter enters the internal iliac artery at approximately 5 to 6 cm. At this depth, the

**Figure 184-2** Approximate distances for catheter insertion, with radiographic confirmation of proper placement after insertion. **A,** Umbilical artery catheter (avoid inserting to level of aortic valve). **B,** Umbilical vein catheter. (From Johns Hopkins Hospital; Siberry G, Iannone R [eds]: The Harriet Lane Handbook: A Manual for Pediatric House Officers, 15th ed. St. Louis, Mosby, 2000.)

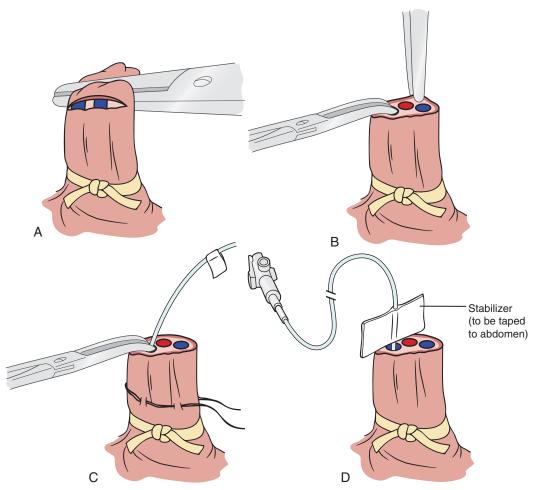

Figure 184-3 Umbilical artery catheter placement. **A,** The cord is transected approximately I cm above the umbilical tape. **B,** The desired artery is dilated with small curved forceps. **C,** The catheter is inserted through the vessel lumen to the length previously measured and secured with a silk pursestring suture. **D,** Alternatively, the catheter can be secured by a stabilizer taped to the abdomen.

catheter must turn cephalad. Twisting the catheter slightly may also help overcome resistance. Occasionally, resistance from vasospasm may be overcome by applying constant gentle pressure for 30 to 60 seconds, causing the spasm to subside. Another technique for relieving vasospasm is to fill the tip of the catheter with 2% lidocaine and then to flush some of it at the level where the resistance is noted. After waiting 1 to 2 minutes, attempt to advance the catheter again. Do *not* advance against significant resistance, especially at a depth of 4 to 5 cm. Resistance at this depth generally indicates that a false tract has been created. Rather than continuing to advance the catheter, withdraw it and attempt to cannulate the other artery.

- UVC. Insert in the same manner as a UAC. At the insertion depth previously determined, CVP can be measured, hyperalimentation solutions can be administered, and medications can be infused. If an obstruction is encountered at a depth of 5 to 10 cm, the catheter has probably entered a branch of the portal vein of the liver and should be withdrawn.
- 8. Secure the catheter with the umbilical tape. Also use a silk suture in a pursestring fashion (see Fig. 184-3C), or with a stabilizer (Fig. 184-3D). Once the sterile field is taken away, the catheter may not be advanced. For that reason, it is often more convenient to insert the catheter slightly further than necessary. (For a UAC, never exceed the distance to the aortic valve [see Fig. 184-2].) Then it can be withdrawn slightly after radiographic confirmation of the location of the tip.

**NOTE:** Occasionally a persistent urachus in the umbilical stump is mistaken for the umbilical vein. Catheterization of the urachus results in the return of urine instead of blood and is easily identified and corrected.

- Apply sterile gauze over the antibiotic ointment and tape the catheter to the abdomen.
- 10. Obtain radiographic confirmation of proper placement. Again, the ideal location of the UAC tip is either high placement at T6–T9 (above the diaphragm and the celiac axis but below the ductus arteriosus) or low placement at L3–L5 (above the aortic bifurcation but below the inferior mesenteric artery). If radiographic confirmation is not possible, a UVC should be used instead of a UAC and should be inserted only 3 to 5 cm or until prompt return of blood is noted.
- Check the catheter frequently for patency and the infant for signs of infection. If signs of infection are noted, take cultures from the catheter.
- 12. As soon as the catheter is no longer needed, it should be removed. In addition, remove the catheter in the face of complications. When the catheter is no longer needed for arterial sampling or for CVP monitoring, in some NICUs it is simply pulled out enough to leave the tip in the midline. This maintains peripheral access if it is extremely critical or has been difficult to obtain. At that level, it then can be used for infusions.
- 13. If vasospasm occurs while the UAC is in place, causing ischemia of one buttock or leg, apply warm compresses to the

contralateral limb in an attempt to trigger reflex vasodilation in the affected limb. If no improvement in limb color or pulse is observed in 15 minutes, the catheter should be withdrawn. An attempt can also be made to relieve vasospasm by repositioning the catheter. Withdraw it a short distance or rotate it, while observing limb color. If successful, obtain radiographic confirmation of proper placement. Other options include withdrawing the line completely and catheterizing the other artery or using a smaller catheter in the same artery.

14. For catheter removal, the stopcock should be turned off. Umbilical tape should be tied loosely around the stump. The catheter should then be gradually withdrawn over 3 to 5 minutes. If there is bleeding, tighten the umbilical tape or grasp the vessel with forceps and apply pressure until it stops.

#### **COMPLICATIONS**

- Air embolization (use a three-way stopcock and flush all tubing before connecting)
- Necrotizing enterocolitis
- Bladder rupture
- Pelvic exsanguination
- Exsanguination from disconnected tubing (use locking connectors on tubing, secure the line)
- Bacteremia or sepsis (to minimize risk, remove the catheter once the infant is stabilized or within 5 days)
- Vascular perforation or malformation
- Congestive heart failure
- Fluid around the umbilicus, if the catheter is placed too low or withdrawn too far
- Silent thrombus (difficult to diagnose without contrast studies)
- UAC complications (risk of complications is as high as 10%)
  - Ischemia to bowel, liver or other intraabdominal organ, or lower extremity
  - Systemic hypertension as a result of renovascular stenosis or thrombosis
  - Embolization of clots causing loss of digits, organ infarcts, or skin ulceration
  - Hypoglycemia
- UVC complications (risk of complications is as high as 20%)
  - Portal hypertension
  - Pericardial perforation (if placed in the right atrium for central monitoring)
  - Arrhythmias
  - Hepatic abscess or necrosis
  - Pulmonary embolism

#### POSTPROCEDURE PATIENT EDUCATION

If the procedure is successful, this should be explained to the family. If there were any complications, this should also be explained, as well as what will be done about them. Any questions regarding the umbilical catheter should be answered. The family should be informed of the need for and value of having the catheter in place, and reassured that it will be monitored continuously for any signs of complications. They should be aware that it will be withdrawn

to a safer level or removed as soon as it is no longer needed. It will also be removed at the first signs of a complication. Families also usually appreciate any other reassurances and guidance provided when they have a critically ill loved one in an intensive care setting, especially an infant.

# MUSCULOSKELETAL Ultrasonography

John Hill • Mark Lavallee • Grant C. Fowler

Ultrasonography has been used to assess the musculoskeletal system since the 1980s. The diagnostic and interventional aspects of this imaging modality were once the sole province of radiologists, and it was used primarily in Europe (especially the United Kingdom) and Canada for these applications. This technology was not largely embraced by radiologists in the United States because it was overshadowed by the growth of computed tomography (CT) and magnetic resonance imaging (MRI). However, additional innovations in instrumentation, advances in clinical applications, and availability of clinician training programs have led us out of the infancy of musculoskeletal ultrasonography (MSK US). These technologic improvements, combined with increasing recognition of the benefits over traditional CT and MRI (e.g., less cost, higher patient satisfaction, ease of use, dynamic capabilities including guiding interventions), have led to a resurgence of interest. Primary care clinicians, particularly those skilled in sports medicine, are applying their knowledge of anatomy and pathophysiology to use this diagnostic tool as an extension of the history and physical examination. The diagnostic applications for MSK US in the upper and lower extremities and for special populations, including pediatric patients, are immense. There are also a significant number of procedural applications. To cover every joint and procedural application of MSK US would be beyond the scope of this book; therefore, this chapter addresses some of the more common clinical uses.

# **TECHNOLOGY AND TERMINOLOGY**

Various terms are used to describe ultrasonographic equipment and images. B-mode US refers to brightness mode, and it allows real-time imaging. B-mode US is the precursor to gray-scale US and is somewhat limited beyond differentiating fluid from solid; consequently, it has largely been replaced by gray-scale US. Gray-scale US differentiates between intensities of echoes and displays them in black, white, and various shades of gray, which improves not only the resolution of the images but the ability to distinguish between different types of tissue. However, even gray-scale US cannot differentiate between fibrous synovial tissue and active synovitis; such a differentiation requires characterization of blood flow. Color Doppler US uses the principle that sound waves increase in frequency when they reflect from objects moving toward the transducer and decrease when they reflect from objects moving away. This is combined with real-time imaging to indicate the presence and direction of blood flow. Red signals indicate flow toward the transducer and blue signals indicate blood flow away from the probe. Power Doppler US has increased sensitivity for imaging small vessels and slow blood flow, which better demonstrates hyperemia and can help differentiate between inflammatory (hyperemic) and scar tissue. Power Doppler US may help visualize neovascularization or angiogenesis

in inflamed or otherwise affected tissues (e.g., chronic tendinosis). Both color and power Doppler US allow one to clearly differentiate cystic lesions from vessels. (See also Chapter 225, Emergency Department, Hospitalist, and Office Ultrasonography [Clinical Ultrasonography], for discussions of principles of ultrasound and beginner scanning. Quality assurance, credentialing, and liability are also discussed.)

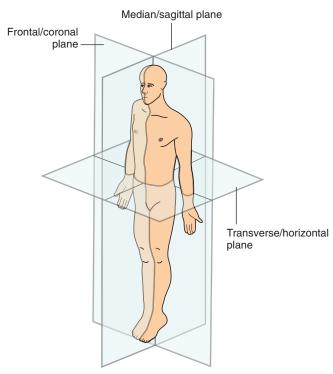

MSK US should be performed with a high-resolution linear-array transducer with frequencies between 7.5 and 20 MHz. The lower frequencies allow visualization of the deeper structures (e.g., hip joint), whereas the higher frequencies are better for superficial structures (e.g., finger joints). In addition to gray-scale US, machines with tissue harmonic imaging or compound imaging are useful for musculoskeletal applications. Advances in ultrasonographic equipment mirror changes in computer technology, and the actual machine used does not have to be the latest version. Although the newer machines have more features and are more portable, they are more expensive. To reduce startup costs, instead of purchasing a new machine, it may be possible to purchase a high-frequency lineararray transducer for a machine already owned or to purchase a used machine when someone else upgrades his or her equipment. Standoff probe attachments are available to enhance resolution in certain older equipment; they are also useful with most equipment when scanning very superficial structures.

#### **ORIENTATION AND ANATOMY**

Ultrasonographic scans are defined by two views oriented perpendicular to one another, the *transverse/axial/short-axis view* and the *longitudinal/long-axis view* (Fig. 185-1). Long-axis images are further defined as *sagittal* or *coronal*. Understanding anatomy as viewed by ultrasonography is a "learned skill" that takes both patience and practice to acquire. One must keep two principles in mind. First, three-dimensional structures are seen on a screen in only two dimensions. Second, a 90-degree turn of the probe will change the orientation of a two-dimensional view from axial (short axis) to longitudinal (long axis) or vice versa.

# **SCANNING**

The position of the probe in the practitioner's hand is variable; many hold it as a large pencil or like a computer mouse (Fig. 185-2). Artifact is minimized by keeping the probe as perpendicular as possible to the tissue being scanned. By convention, solid or echogenic tissue or structures are whiter on the image, whereas fluid or fluid-filled tissue or structures are darker, hypoechoic, or echolucent. Table 185-1 shows some common superficial anatomic structures seen with MSK US as well as the common views used to scan these structures.

**Figure 185-1** Short-axis (transverse/axial) and long-axis (longitudinal/sagittal/coronal) views in ultrasonographic scanning.

#### **INDICATIONS**

See Table 185-2.

#### **PRECAUTIONS AND CONTRAINDICATIONS**

Diagnostic MSK US is a safe imaging modality with no exposure to radiation, no risks of a large magnet disrupting vascular clips, and no issues related to claustrophobia. The fact that ultrasonography has been used for years in maternal-fetal medicine with no documented ill effects speaks to its safety. Therefore, the major precaution is related to the imaging abilities; this procedure is highly operator and interpreter dependent. The sensitivity and specificity are related to the ability to visualize the individual structures and, once these are seen, to distinguish normal from abnormal anatomy. It is quite easy to visualize and diagnose an inflamed biceps tendon; however, it can be quite difficult to differentiate between chronic hamstring inflammation and a high hamstring injury. Clinicians must know their limitations and caution must be used to avoid scanning, diagnosing, or performing procedures beyond their skills.

Figure 185-2 Hand and probe position.

Although procedures performed using ultrasonographic guidance are safer than blindly performing injections and aspirations, whenever a needle enters the skin, there are inherent risks of pain, bleeding, infection, and damage to underlying or surrounding tissues. No absolute contraindications to MSK US exist, but similar to all procedures, using good judgment and proper techniques will protect you and your patient.

# **EQUIPMENT**

- Ultrasonography machine with a high-frequency (7.5 to 20 MHz), high-resolution, linear-array transducer able to capture images (see Suppliers section). Standoff disks are available to artificially increase the transducer frequency.
- Printer paper for images.
- Ultrasonic gel.
- Towels to drape the area and for cleanup afterward.
- Equipment necessary to perform procedure such as sterilizing solution (alcohol, povidone-iodine [Betadine], chlorhexidine [Hibiclens]), sterile needles, local anesthetic, or any necessary instruments.

**NOTE:** Linear-array transducers do have one significant limitation: they accentuate anisotropy. This hypoechogenic artifact of the tendon insertions can look like a tendon tear (Fig. 185-3); it is due to the lack of divergent beam geometry.

# PREPROCEDURE PATIENT EDUCATION AND PREPARATION

Diagnostic ultrasonography, and any possible ultrasonographyguided procedure, should be briefly explained to the patient (or representative) before obtaining consent verbally and often in writing. The approximate length of time to accomplish the procedure, the few risks involved (e.g., irritation from ultrasonic gel, having to remain still during the examination, missed diagnosis), the amount of discomfort to expect from an ultrasonographydirected procedure, the benefits of having this procedure, and any alternatives should be explained. For an ultrasonography-guided procedure, any additional risks should be explained (e.g., risks of infection, injury to a nearby structure such as a vessel or nerve, scar formation, tendon rupture, hematoma) as well as any alternatives. Any other aspects should be addressed, depending on the practitioner's personal style (e.g., some clinicians curtail use of nonsteroidal anti-inflammatory drugs [NSAIDs] or aspirin before certain procedures [e.g., dry-needling tendon]; other clinicians use topical ethyl chloride "cold" spray before needling instead of injecting an anesthetic). The cost should also be explained, especially for Medicare patients; a Medicare waiver should be signed. There may be benefit to discussing postprocedure expectations at this point, especially those regarding activity, physical therapy, and restrictions. The patient should know that the room lights may be dimmed to improve visualization of the screen. (See the sample forms online at www.expertconsult.com for checklists for diagnostic and ultrasonography-guided procedures.)

# **TECHNIQUE**

# Overall

1. There are several prerequisites essential to performing adequate MSK US; these should be ensured before scanning. Enough time should have been allocated to provide the imaging and perform the procedure (10 to 60 minutes). There must be adequate support staff, and they can help prepare the patient (e.g., obtain informed consent, appropriately uncover the body part to be

Shoulder Elbow, wrist and hand, hip, knee, ankle and foot Prosthetic hip Foot Peripheral nerves Soft tissue mass Soft tissue foreign body Interventional ultrasound/Ultrasound-guided procedures	entrapment, joint effusion, foreign body, bone in Joint effusion and extra-articular fluid collection (ofte Morton's neuroma, plantar fasciitis Compression neuropathies, neuritis, nerve mass, n Differentiating cystic from solid mass; determining s Detection and localization of foreign body, especiall types of glass Aspiration of cysts, fluid collection or abscess; arthro	en for ultrasound-guided aspiration)

ABI, autologous blood injection; PRPI, platelet-rich plasma injection; UCL, ulnocollateral ligament.

imaged), turn on the machine, and record the patient's demographic information. Often an assistant is needed to operate the machine during a procedure because the clinician's hands may be occupied with the probe and needle. Both the patient and clinician should be positioned in a manner that will be comfortable for the duration of the procedure. Any additional questions should be answered before starting the procedure.

- 2. Apply ultrasonic gel to the patient's skin. If planning an ultrasonography-guided percutaneous procedure, certain additional steps should be taken.
  - Apply a sterile cover over the probe/transducer (a sterile glove can be used). Some clinicians apply a small ribbon of gel to the probe before applying the sterile cover.
  - Cleanse the area of skin with antiseptic solution.

**Figure 185-3** Anisotropy (arrow) of supraspinatus insertion on greater tuberosity (GT). HUM, humerus.

- Apply to the area any of the following:
   Sterile ultrasonic gel
   Packet of sterile KY Jelly
   Betadine-impregnated gel (if you are not using a disposable probe cover, this will stain the transducer)
- Apply sterile probe to site.

**NOTE:** Preferably a sterile probe cover should be over the probe.

- 3. Capture basic images (Table 185-3 shows some common sono-graphic pathologic findings):
  - Identify large and obvious structures first.
  - Get into the habit of viewing most structures in both transverse and longitudinal planes.
  - When needed, capture images of the area in question in both static and dynamic positions (i.e., relaxed and contracted or flexed and extended).
  - Consider using color or power Doppler to look for blood flow in low- to high-flow states to assess for inflammation or neovascularization, or to differentiate between a cyst and a vessel.
  - When performing percutaneous needling (aspiration/injection or dry needling), try to obtain and document images. Because the clinician's hands will be occupied with the probe and syringe (Fig. 185-4), an assistant may be needed to run the machine.
- 4. Postprocedure: Once the procedure is completed, wipe the ultrasonic gel off of the patient and the probe.
  - It is important to remove the gel before it dries.
  - If a percutaneous procedure has been performed, remove and discard the sterile cover. Clean the probe head with manufacturer's approved cleaning solution.

TABLE 185-3 Common Sono	ographic Pathologic Findings		
Diagnosis	Views Needed	Characteristics	Example
Full-thickness supraspinatus tear	Coronal, adduction, and abduction	Retraction of supraspinatus muscle, disrupted tendon	•
Calcific tendinopathy of supraspinatus	Longitudinal and axial	Intense echogenic mass within tendon; shadowing below mass similar to bone shadows	
Chronic, partial-thickness supraspinatus tear	Coronal, adduction, and abduction	Hypoechoic defect within supraspinatus tendon, but no complete disruption	the state of the s
Lateral epicondylitis (tennis elbow)	Longitudinal and axial	Hypoechoic (edema) and thickening within normal tendon	
Thumb, UCL partial-thickness tear (skier's thumb)	Longitudinal and stress	Hypoechoic thickened tendon with joint laxity on stress	UCL Sprain
Soft tissue abscess	Longitudinal and axial	Hypoechoic cystic structure with bright internal echoes	* ×
Long head of biceps tendon rupture (large arrow)	Longitudinal and axial	Tendon disrupted and hypoechoic fluid replacement within tendon sheath	

TABLE 185-3 Com	mon Sonographic Pathologic Findings-	—cont.	
Diagnosis	Views Needed	Characteristics	Example

Ligaments, lateral collateral	Longitudinal	Lateral collateral ligament disruption	* 0.03cm  RT LAT UT SPACE LCL

UCL, ulnocollateral ligament.

 If blood, body fluids, or Betadine somehow gets onto the probe surface, wash it with soap and water and then follow the manufacturer's recommendation to disinfect the probe.

**NOTE:** Povidone–iodine, if allowed to stay on the probe even for a short length of time, will discolor the probe and may shorten its working life.

 Complete and save any documentation on the ultrasonography unit and in the patient's chart.

#### **Specific**

#### Shoulder

1. To examine the biceps tendon, the patient's hand should be in the supine position and resting on the thigh or a pillow on the examination table with the arm slightly rotated externally. To localize the tendon, it can be scanned transversely, from where it emerges under the acromion, and followed distally to where it inserts. The tendon should then be scanned longitudinally. While scanning, determine whether the tendon is properly located in the bicipital groove, or if it can be subluxated or dislocated. Also, attempt to determine whether it is torn or disrupted.

**Figure 185-4** Example of positioning for an ultrasonography-guided injection.

- 2. To scan the subscapularis tendon, the patient's elbow should be by the side and the arm externally rotated. The tendon should be scanned transversely and then longitudinally. It may be helpful to observe the tendon as the patient moves the arm from externally to internally rotated.
- 3. To scan the supraspinatus tendon, ask the patient to place the hand in his or her back pocket on the same side. In this position, the elbow will be flexed, the arm extended posteriorly, and the palm of the hand placed against the posterior pelvis (iliac wing). The tendon should be scanned longitudinally and then transversely. The infraspinatus tendon can be scanned with the arm in the same location. The probe can be placed anteriorly and posteriorly to get longitudinal scans of both tendons, and will usually need to be angled 45 degrees to the sagittal plane, or in between the sagittal and coronal planes, to obtain good views. Transverse images are then obtained by rotating the probe 90 degrees. Sweep the transducer over the tendons laterally from the acromion to their insertion on the greater tuberosity of the humerus.
- 4. The arm is then returned to rest supinated on the thigh. In this position, the most posterior aspect of the infraspinatus tendon can be scanned as well as the posterior teres minor tendon. Internal and external rotation of the arm will help identify the infraspinatus tendon. The probe will usually need to be directed inferiorly to evaluate the entire teres minor tendon.
- 5. Scan also the posterior aspect of the glenohumeral joint below the scapular spine, perhaps while internally and externally rotating the arm. Small joint effusions may be noted with the transducer in this position.
- 6. When scanning the rotator cuff tendons, comparison with the contralateral side may be useful. Also, be on the alert for tendon calcification, bursal thickening, or loose bodies. Compression of the cuff may help identify nonretracting tears.

# **Elbow**

 For scanning, the elbow is divided into anterior, posterior, medial, and lateral quadrants. The patient should be sitting or lying with the hand supine and the arm extended.

- 2. To scan the anterior elbow, the bicipital tendon can first be followed down to its insertion on the radial bicipital tuberosity. Next, assess the articular cartilage and cortical bone while scanning the anterior humeroradial and humeroulnar joints and the coronoid and radial fossae, both longitudinally and transversely. Also look for joint effusions, synovial thickening, or loose bodies. Note the brachialis muscle, the adjacent radial and brachial nerves and vessels, as well as the median nerve. While the patient is supinating and pronating the forearm, scan the annular recess of the neck of the radius.
- 3. To scan the lateral elbow, have the patient put both palms together if sitting; if lying, have him or her place the forearm across the abdomen. Scan the lateral epicondyle and the attachments of the common extensor tendon, extensor carpi radialis longus, and brachioradialis. The radial collateral ligament is then scanned by having the patient pronate the hand while the transducer is on the posterolateral aspect of the elbow.
- 4. The medial elbow is scanned with the hand in the supine position. The medial epicondyle, common flexor tendon, and ulnar collateral ligaments should be scanned in longitudinal and transverse planes. While scanning, the integrity of the ulnar collateral ligament can be tested by applying valgus stress with the elbow slightly flexed. Scan the ulnar nerve in the cubital tunnel between the olecranon process and the medial epicondyle. Test for ulnar nerve subluxation by scanning while the patient flexes and extends the elbow.
- 5. Scan the posterior elbow by placing the palm down on the examination table (if the patient is sitting) or by placing the forearm across the abdomen with the elbow flexed 90 degrees (if the patient is lying). Scan the posterior joint space, the triceps tendon, the olecranon process, and the olecranon bursa in both longitudinal and transverse planes.

#### Wrist

- 1. The wrist is scanned from volar, ulnar, and dorsal locations.
- 2. To scan the volar wrist, the hand is placed on the examination table (if the patient is sitting) or pillow (if the patient is lying) with the palm up. Slight dorsiflexion may facilitate scanning. Scan from the wrist crease distally to the thenar muscles in both longitudinal and transverse planes. Within the carpal tunnel, the flexor retinaculum, the flexor digitorum profundus, and superficialis tendons, and the adjacent flexor pollicis longus tendons, should be identified. The median nerve lies superficial to these tendons but deep to the retinaculum. Flexion and extension of the fingers will demonstrate normal motion of these tendons and, to a lesser degree, the median nerve. Superficial to the retinaculum is the palmaris longus tendon. On the ulnar side of the wrist, branches of the ulnar nerve and artery lie within Guyon's canal. The flexor carpi ulnaris tendon borders the ulnar aspect of Guyon's canal. On the radial side of the wrist, the flexor carpi radialis longus tendon lies in its own canal. Whichever tendon is clinically indicated should be scanned for integrity, both longitudinally and transversely, to its site of insertion. Occult ganglion cysts can occasionally be noted originating from the radiocarpal joint capsule.
- 3. On the ulnar side, the triangular fibrocartilage can be scanned in its long axis by placing the transducer in a transverse position and scanning distal to the ulnar styloid. Rotating it 90 degrees allows for scanning the cartilage in short axis. The meniscus homolog lies distal to the triangular fibrocartilage and deep to the extensor carpi ulnaris longus tendon. This tendon should also be scanned for subluxation by pronating and supinating the wrist.
- 4. Dorsal scanning may be facilitated by placing the wrist in slight volar flexion. Structures on the dorsal wrist are very superficial, and the extensor retinaculum divides the dorsal wrist into six compartments. These compartments contain nine tendons that should be scanned longitudinally and transversely, at rest and in

motion, to their point of insertion, as clinically indicated. With the transducer turned transversely, the scapholunate ligament can be scanned distal to Lister's tubercle. This is a common site for ganglion cysts and ligamentous tears. Otherwise, the remaining intercarpal ligaments are not routinely assessed. With an inflammatory arthritis, the metacarpophalangeal joints and, if symptomatic, the proximal interphalangeal joints can be scanned, both longitudinally and transversely. The clinician should look for effusions, synovial hypertrophy, or bony erosion. Color and power Doppler may be useful for detecting synovial hyperemia. Because the structures on the dorsal wrist are very superficial, a standoff pad may be helpful.

#### Нiр

- The hip can be scanned from anterior, posterior, medial, or lateral locations. In adults, a lower-frequency probe may be necessary for adequate tissue penetration; however, use the highestfrequency probe that will allow visualization of the deeper structures.
- 2. To scan from the anterior location, the patient should be supine with the hip rotated slightly externally. Scan longitudinally along the femoral head and neck. Evaluate the joint for any signs of an effusion, and then evaluate the labrum, the iliopsoas tendon and bursa, and the sartorius and rectus femoris muscles. These structures should also be scanned in short-axis views. The femoral vessels can be scanned. An anterior "snapping hip" is sometimes caused by the iliopsoas muscle tendon where it passes over the superior pubic bone.
- 3. To scan from the lateral location, rotate the patient to the lateral decubitus position with the symptomatic side up. Scan the greater trochanter, the greater trochanteric bursa, the tensor fascia lata, and the glutei medii, maximi, and minimi, all longitudinally and then transversely. Another type of snapping hip can be diagnosed when scanning from this position if the iliotibial tract snaps when passing over the greater trochanter while the hip is being moved from extension to flexion, or vice versa.
- 4. To scan from the medial location, the hip is placed in the frog-leg position (externally rotated with 45 degrees of knee flexion). The abductor muscles can be scanned longitudinally, as well as the distal iliopsoas tendon, and then in their short-axis plane. The pubic bone and symphysis as well as the distal insertion of the rectus abdominis on the pubic bone should be scanned from this position.
- 5. To scan from the posterior position, the patient should be turned to the prone position with the leg extended slightly. The glutei, hamstrings, and sciatic nerve can be scanned longitudinally and then transversely. The glutei can be scanned from origin to insertion on the greater trochanter (minimus and medius) or linea aspera (maximus). The sciatic nerve can be followed from its exit under the greater sciatic foramen, deep to the gluteus maximus muscle, and then distally to where it lies superficial to the quadratus femoris muscle. Along its course, it lies midway between the ischial tuberosity and the greater trochanter. It should be scanned both longitudinally and transversely.
- 6. The prosthetic hip is typically scanned for the presence of an effusion or extra-articular fluid collection. It is usually scanned from the anterior or lateral location, as described previously, and effusions are usually located at the prosthesis—bone junction. Any effusions should be measured and documented. The greater trochanteric and iliopsoas bursae should also be scanned for the presence of fluid.

#### Knee

- The knee is also divided into anterior, medial, lateral, and posterior quadrants when scanning.
- To scan the anterior knee, the patient is usually supine with the knee flexed 30 degrees. Longitudinal and transverse scans are

obtained of the quadriceps and patellar tendons, the patellar retinacula, and the suprapatellar recess. The prepatellar, superficial, and infrapatellar bursae should also be evaluated. The patella can be scanned for occult injury if clinically indicated. With the knee in maximal flexion and the transducer in the transverse plane, the suprapatellar recess can be scanned and the distal femoral cartilage assessed. This cartilage can also be assessed using longitudinal scans over the medial and lateral condyles, if indicated. While maintaining the knee in maximal flexion, the distal anterior cruciate ligament can be followed longitudinally with the probe to its insertion into the anteromedial tibial plateau.

- 3. To scan the medial knee, the patient remains supine with the knee slightly flexed and the hip slightly externally rotated. Alternatively, the patient can be in the lateral decubitus position with the affected knee located inferiorly. Scan the medial joint space in both longitudinal and transverse planes. The medial collateral ligament, the pes anserine tendons and bursa, and the medial patellar retinaculum should be evaluated. The anterior body and horn of the medial meniscus can be scanned from this position, possibly facilitated by the application of some valgus stress.
- 4. To scan the lateral knee, the patient may remain supine with the ipsilateral leg internally rotated or in the lateral decubitus position with the affected knee located superiorly. Placing a pillow between the knees may increase patient comfort. Scanning longitudinally and transversely, and moving from posterior to anterior, the popliteus tendon, fibular collateral ligament, iliotibial band, and bursa should be evaluated. The lateral patellar retinaculum can also be assessed from this location. The lateral meniscus can be evaluated by scanning in the joint line.
- 5. The posterior knee is scanned with the patient lying prone and the leg slightly extended. Scanning both longitudinally and transversely, the popliteal fossa and the semimembranosus and medial and lateral gastrocnemius muscles, tendons, and bursae can be assessed. The posterior horns of both menisci can be assessed by scanning transversely from this location, and the posterior cruciate ligament can be followed longitudinally. The superior aspect of the anterior cruciate ligament can be assessed somewhat when scanning transversely in the intercondylar region. To confirm a popliteal cyst, it should be demonstrated to originate from the posterior joint capsule between the medial head of the gastrocnemius tendon and the semimembranosus tendon when scanning transversely.

#### Ankle

- The ankle is divided into the anterior, medial, lateral, and posterior quadrants.
- 2. To scan the anterior quadrant, the patient lies supine with the knee flexed and the foot flat on the examination table. From medial to lateral, the tibialis anterior, extensor hallucis longus, extensor digitorum longus, and peroneus tertius (occasionally congenitally absent) tendons are scanned in longitudinal and transverse planes. They should be followed from their musculotendinous origins to their distal insertions. The anterior joint recess is scanned for effusions, loose bodies, and synovial thickening. It may need to be compared with the contralateral side joint recess. The anterior joint capsule is attached to the anterior tibial margin, superiorly, and the neck of the talus, inferiorly. The cartilage of the talus appears as a thin, hypoechoic line. Assess the anterior tibiofibular ligament by moving the transducer over the distal tibia and fibula, superior and medial to the lateral malleolus, and scanning in an oblique transverse plane.
- 3. The medial ankle can be scanned with the patient in the same position. Scanning from anterior to posterior with the transducer in the transverse position, the posterior tibial, flexor digitorum longus, and flexor hallucis longus tendons can be located proximal to the medial malleolus. They can then be scanned transversely and longitudinally from their muscle of origin above the

- malleolus to their distal insertions. The probe angle may need to be varied to follow the tendon around the medial malleolus. The tibial nerve can then be identified at the level of the malleolus where it travels between the tendons of the flexor digitorum, anteriorly, and flexor hallucis longus, posterior to it. The nerve can be followed proximally and distally. The flexor hallucis longus can also be scanned in the posterior position where it lies medial to the Achilles tendon. The deltoid ligament is then scanned longitudinally from the medial malleolus to its attachments on the navicular, talus, and calcaneus bones.
- The ankle is scanned from the lateral location with the patient in the same position. Slight inversion of the foot may facilitate scanning. Scanning transversely, proximal to the lateral malleolus, the peroneus brevis and longus tendons are usually easy to identify. They can then be scanned transversely and longitudinally from their proximal muscle of origin to their distal insertion. The peroneus longus tendon can be followed to the cuboid groove, where it turns to course medially along the plantar aspect of the foot to insert at the base of the first metatarsal and medial cuneiform. The peroneus brevis tendon is followed to its insertion on the base of the fifth metatarsal. These tendons should be assessed for subluxation by scanning while dorsiflexing and everting the foot. The lateral ligament complex is then assessed by placing the transducer on the tip of the lateral malleolus. From this position, the transducer will need to be turned out of the strict sagittal plane to scan and follow the anterior and posterior talofibular and calcaneofibular ligaments longitudinally.
- 5. The posterior ankle is scanned with the patient supine and the foot extended over the end of the examination table. Scan the Achilles tendon longitudinally and transversely from its origin, the medial and lateral heads of the gastrocnemius and soleus muscles, to its insertion on the posterior surface of the calcaneus. Plantar flexion and dorsiflexion of the foot while scanning may assist in the diagnosis of a tear. Along the medial aspect of the Achilles, the plantaris tendon may be noted to insert on the posteromedial calcaneus. Although absence of this tendon may be a normal variant, it often remains intact despite a full-thickness Achilles tendon tear. The retrocalcaneal bursa deep to the Achilles tendon can also be scanned. The plantar fascia should be scanned transversely and longitudinally from its origin on the medial calcaneal tubercle to where it divides distally and merges with soft tissue.

#### Foot

- Similar to the hand, in patients with inflammatory arthritis, the
  metatarsophalangeal joints can be scanned, as well as the proximal interphalangeal joints if symptomatic, looking for effusions,
  synovial hypertrophy or hyperemia, or bony erosions. These
  joints, as well as any other symptomatic joints in the foot, should
  be scanned longitudinally and transversely. They can be scanned
  from dorsal or plantar locations.
- 2. The interdigital spaces of the foot can be scanned from either dorsal or plantar locations. Starting at the level of the first interdigital space, with the transducer in the longitudinal orientation, the interdigital spaces are scanned while moving the transducer laterally. The same areas should also be scanned transversely. The intermetatarsal bursa lies on the dorsal aspect of the interdigital nerve, so care must be taken to differentiate it from a Morton's neuroma. Pressure can be applied to reproduce the symptoms with a Morton's neuroma.

# Peripheral Nerves

 Common peripheral nerve problems include entrapment and subluxation. The most common locations for entrapment are within fibro-osseous tunnels such as the cubital or Guyon's tunnel for the ulnar nerve, the carpal tunnel for the median nerve, the tarsal tunnel for the tibial nerve, or the tunnel formed by the fibular neck and the common peroneal nerve. The most

- common subluxating nerve is the ulnar nerve in the cubital tunnel.
- 2. Nerves course adjacent to tendons and vessels, and Doppler ultrasonography can be used to distinguish them from vessels. Tendons can be distinguished by the fact that they move much more readily than nerves with flexion or extension of the nearest joint. Surrounded longitudinally by hyperechoic fascicles, nerves are usually hypoechoic and may be interspersed with hyperechoic endoneurium or further surrounded by hyperechoic epineurium. It may be easier to follow the course of a nerve and to differentiate it from nearby tendons by scanning transversely, at first, and then scanning longitudinally.
- 3. For an entrapment neuropathy, after locating the nerve in the tunnel, nearby tissues (e.g., tendons, soft tissue, bones) should be scanned in an attempt to identify the source of entrapment.
- 4. A statically dislocated nerve is usually readily identified with ultrasonography; however, an intermittently subluxating nerve may need to be imaged during flexion or extension of a nearby joint.

#### Soft Tissue Masses

A soft tissue mass should be scanned longitudinally and transversely, and diameters measured in three planes. Cysts should be differentiated from solid masses, and nearby structures should be determined, particularly neurovascular bundles, bones, tendons, and joints. Compressibility of the mass should be determined. Vascularity can be evaluated using Doppler.

#### Foreign Bodies

When scanning a foreign body, the approximate size, location, and nearby structures should be determined. Most foreign bodies larger than a certain diameter (depending on the frequency and quality of the probe) will cast an acoustic shadow or a comet tail artifact. A standoff pad may be needed for the probe to scan very superficial foreign bodies in subcutaneous tissues. (See also Chapter 225, Emergency Department, Hospitalist, and Office Ultrasonography [Clinical Ultrasonography].)

# Interventional Ultrasonography

- 1. Ultrasonography provides direct visualization of the needle pathway, and if the probe is equipped with a needle guide, it may provide direct visualization of the needle and show the position of the needle as it enters the target area.
- 2. Nearby structures should be evaluated, in an attempt to avoid them, and the shortest pathway to the interventional site is usually determined. For ultrasonography-guided biopsy, focal areas of vascularity may indicate viable tissue.
- 3. Ultrasonography-guided procedures can be performed either statically or in real time. For statically guided interventions, the insertion site, angle, and depth are initially identified with ultrasonography and then the probe is laid aside while the procedure is performed. For real-time guidance, the procedure is performed with simultaneous ultrasonographic imaging. Either a one-person or two-person technique can be used for ultrasonography-guided procedures. (See also Chapter 225, Emergency Department, Hospitalist, and Office Ultrasonography [Clinical Ultrasonography].)

# SAMPLE OPERATIVE REPORT

Diagnostic: Patient (or patient's proxy) was informed about the protocol and the risks of having a diagnostic ultrasound. Written informed consent was obtained. Longitudinal and axial views were captured, reviewed, measured, and archived. Doppler ultrasound views were also obtained and the following vascular structures were identified. The following anatomic structures were seen via ultrasound, and noted caliper measurements were archived. Images of the area in question were viewed both in a relaxed (or static) phase and also in a contracted (or dynamic) phase, cap-

PRP, platelet-rich plasma.

tured and archived. No complications were noted from this scan, and the patient tolerated the procedure well. Results were explained to the patient before discharge from the office. [Finally, the impression should state a defined diagnosis and the plan should include any pertinent instructions.]

Percutaneous needling: Patient (or patient's proxy) was informed verbally about the protocol and the risks of having this procedure performed as well as having a diagnostic ultrasound. Written informed consent was obtained. Topical ethyl fluoride or local lidocaine was used for anesthesia. Normal sterile preparation of both patient and equipment was done using antiseptic solutions and sterile barrier devices. Pre- and postpercutaneous images were reviewed, measured, and archived. Images of the needle in the appropriate location were viewed and documented (Table 185-4).

There were no complications, adverse reactions, or premature termination of this procedure. [Finally, the impression should state a defined diagnosis and the result of the procedure, and the plan should include any pertinent instructions.]

**NOTE:** Images should be saved when billing for an ultrasonographyguided procedure.

# **COMMON ERRORS**

Musculoskeletal ultrasonography is often considered the most operator-dependent imaging technique available. In other words, the most common errors in using this tool are using it incorrectly and incorrectly interpreting the images. In Europe, standardized training courses are available, taught by experienced sonographers, and a set preceptorship period is established after the introductory course. At the conclusion of training, individuals are assessed on their ability to make ultrasonographic diagnoses; thus, interoperator variability is minimized. Standardized teaching methods are lacking in the United States. The American Institute of Ultrasound in Medicine (AIUM) has a set of practice guidelines for the performance of MSK US. These guidelines have been developed to provide practitioners with the minimum requirements for performing diagnostic procedures. Although it is not possible to detect every abnormality, by using a standardized approach one can maximize the ability to detect most problems. These guidelines specifically address examinations of the shoulder, elbow, wrist, hand, hip, knee, ankle, foot, peripheral nerves, and soft tissue masses, as well as the performance of interventional MSK US.

To avoid obvious errors, general scanning principles should be followed that require axial/transverse and longitudinal views of each structure. In an axial scan, one might see a structure that looks like a fluid-filled cyst; however, in the longitudinal image it will be obvious that the structure is in fact a vessel. A full understanding of the underlying anatomy and common abnormalities that might be relevant will increase the operator's scanning sensitivity and accuracy.

# **COMPLICATIONS**

Ultrasonography is generally a safe procedure; the main complication is misdiagnosis. If, when evaluating a shoulder injury, an acute full-thickness supraspinatus tendon tear is missed, surgery could be delayed, which could ultimately lead to a less-than-ideal outcome. If performing an ultrasonography-guided injection, one must follow the usual standards for all interventional procedures: appropriate consent, sterile technique, and, to avoid damage to nerves and vessels, proper positioning of the needle.

# POSTPROCEDURE MANAGEMENT AND PATIENT EDUCATION

The patient should be repositioned into a comfortable position and the results of the ultrasonographic examination explained. At this point, some clinicians review the images with their patients. Future patient care management should also be discussed based on the results.

If an ultrasonography-guided procedure was performed, the postprocedure plan should be reviewed with the patient. The patient should know to watch for signs of infection, increasing pain or swelling, or fever, and know how to reaccess medical personnel if necessary. After aspiration, the patient should know to watch for reaccumulation of aspirated fluid. A pressure dressing for 1 to 3 days may prevent this. Depending on the clinician, restrictive dressings, bracing, immobilizers, sterile bandages, and limits on bathing or activity may be recommended. These are best communicated in writing and shared with the patient and his or her responsible friend or family member. Certain procedures may benefit from a 24 to 48 hours' postprocedure check in the office to assess for pain control. development of a hematoma, or signs of infection. As with many procedures in musculoskeletal medicine, certain home exercises and formal physical therapy protocols may be initiated depending on the clinician's personal protocol. Discuss with patients how to control their pain and give them appropriate medications. Many clinicians now avoid NSAIDs or aspirin in the postprocedure phase because of their antiplatelet effects and inhibition of the normal physiologic inflammatory cycle.

Specific instructions may be warranted with certain procedures:

Injection: Look for local reaction to the injected substance (e.g., cortisone, lidocaine, autologous blood, platelet-rich plasma) or development of a hematoma. A pressure dressing for 1 to 3 days may prevent this. Restrictions and expectations should be discussed.

Dry needling and tenotomy: Look for excessive swelling or new-onset hematoma. A pressure dressing for 1 to 3 days may prevent this. Sometimes elevation of the limb, compression dressing, and ice may be needed postprocedure. Limited, short-term extremity immobilization is often recommended when extensive needling is done to protect against tendon/ligament rupture. The role of physical therapy is crucial when dealing with long-standing injuries that have had needling. Restrictions and expectations should be discussed.

#### INTERPRETATION AND RESULTS

See Table 185-3.

# **CPT/BILLING CODES**

- 20550 Injection, single tendon sheath, or ligament
- 20551 Injection, single tendon origin/insertion
- 20552 Injection(s), single or multiple trigger point(s), one or two muscles

- 20553 Injection(s), single or multiple trigger point(s), three or more muscles
- 27096 Injection into sacroiliac joint
- 76880 Diagnostic ultrasound examination of extremity, nonvascular, including image documentation
- 76942 Ultrasound-guided biopsy, aspiration, injection, localization device
- 93922 Color or spectral waveform Doppler of upper or lower extremity arteries, single level

#### **Modifiers**

- 25 To be used with separate E&M code
- 50 Bilateral procedures
- 51 Multiple procedures

# **Coding Example**

If a patient is referred from another clinician for consultation on shoulder pain and you perform a diagnostic MSK US, you can code (99243) for the consultation, use a (25) modifier, and perform a diagnostic MSK US (76880). If you determine the patient has a long head of the biceps tendinopathy and would benefit from an ultrasonography-guided injection of the tendon sheath, then you can add 76942 and 20550 to your procedures.

# **ICD-9-CM DIAGNOSTIC CODES**

- 354.0 Carpal tunnel syndrome
- 354.2 Cubital tunnel syndrome
- 355.5 Tarsal tunnel syndrome
- 355.6 Morton's neuroma
- 355.9 Mononeuritis of unspecified site (e.g., compression neuropathy)
- 682.9 Other cellulitis and abscess, unspecified site
- 718.00 Articular cartilage disorder, site unspecified
- 718.10 Loose body in joint, site unspecified
- 719.00 Effusion of joint, site unspecified
- 719.40 Pain in joint, site unspecified
- 719.60 Other symptoms referable to joint, site unspecified (e.g., snapping hip)
- 726.4 Enthesopathy of wrist and carpus
- 726.5 Enthesopathy of hip
- 726.6 Enthesopathy of knee
- 726.10 Disorders of bursae and tendons in shoulder region, unspecified
- 726.30 Enthesopathy of elbow, unspecified
- 726.33 Olecranon bursitis
- 726.65 Prepatellar bursitis
- 726.70 Enthesopathy of ankle and tarsus, unspecified
- 727.41 Ganglion of joint
- 727.42 Ganglion of tendon sheath
- 727.51 Baker's cyst
- 727.60 Nontraumatic rupture of unspecified tendon
- 727.61 Complete rupture of rotator cuff
- 727.62 Rupture of tendon of biceps
- 727.63 Rupture of extensor tendons of hand and wrist
- 727.64 Rupture of flexor tendons of hand and wrist
- 727.65 Rupture of quadriceps tendon
- 727.66 Rupture of patellar tendon
- 727.67 Rupture of Achilles tendon
- 727.81 Contracture of tendon or tendon sheath
- 727.82 Calcium deposits in tendon and bursa
- 728.4 Laxity of ligament
- 728.5 Hypermobility syndrome
- 728.83 Rupture of muscle, nontraumatic
- 729.6 Residual foreign body in soft tissue
- 729.81 Swelling of limb

# ANKLE AND FOOT SPLINTING, CASTING, AND TAPING

Gregory A. Marolf

Primary care clinicians encounter a wide variety of acute and chronic foot and lower leg injuries that may benefit from immobilization. The value of immobilization as an initial means of therapy has been known for centuries. Treatment of foot and ankle injuries involves an accurate clinical evaluation and, when indicated, radiographic assessment of potential fractures, avulsions, or instability. Casting and cast splinting are commonly used in acute situations and fractures (see Chapter 190, Fracture Care), whereas splinting and taping are probably best used to control chronic instabilities and as adjuncts in rehabilitation. PRICES (protect, rest, ice, compression, elevation, splint) is the mnemonic often utilized when acute immobilization is indicated. It should also be noted that rapid remobilization is an important part of the rehabilitation for most soft tissue injuries to the ankle.

#### **INDICATIONS**

#### **Soft Tissue Injuries**

- Ankle sprains: Treatment options include use of a sugar-tong splint, taping, and braces (stirrup or lace-up type) for support as the patient returns to weight bearing.
- Plantar fasciitis: Immobilization can be achieved with a nocturnal posterior leg splint, which provides a constant stretch to the plantar fascia. (See Chapter 195, Podiatric Procedures, for other treatments, including customized orthotics.)

# **Fractures**

- Tibial or fibular: Stable distal tibial or fibular fractures, including malleolar fractures, can be immobilized with a splint or short-leg walking cast (see Chapter 190, Fracture Care).
- Fifth metatarsal: Immobilize avulsion fractures with a postoperative shoe, posterior splint, or short-leg cast (see Chapter 190, Fracture Care).
- Other: Primary care clinicians may also encounter fractures of the tarsals, or first through fourth metatarsals. When these fractures are nondisplaced and stable, immobilization alone may be appropriate; otherwise, surgical referral may be necessary (see Chapter 190, Fracture Care).

# **Prophylaxis against Injuries**

Ankle taping or bracing may be used as prophylaxis against injury in ankles that need additional stabilization and improved proprioception.

# **CONTRAINDICATIONS**

 Early (premature) casting: Casting before maximal swelling has occurred can cause necrosis and compartment syndrome.

- Open wound: Never place a cast over an open wound because of the potential for infection. If the wound is not too large, a window may be cut in the cast to monitor it.
- Unstable fractures: These fractures need surgical repair; splint only until definitive treatment can be provided.

# BENEFITS OF DIFFERENT TYPES OF IMMOBILIZATION

The type of immobilization used may vary with the location and severity of the injury, patient or clinician preference, and the plan of treatment. The following list of benefits for each option may help when making decisions.

# **Splinting**

- Stability for soft tissue injuries
- Pain relief
- Easily removable to apply ice massage, etc.
- Provides temporary support for patients needing surgery

#### Casting

- Marked stability
- Significant pain relief
- Immobilization for hard-to-treat soft tissue injuries as well as fractures

# **Taping**

- Supports acutely injured ankles
- Supports chronically weak ankles or a chronically injured plantar fascia
- Enhances proprioception
- Prophylaxis against injury

# **EQUIPMENT**

#### Casting

Figure 186-1 illustrates the materials needed for casting.

- Stockinette: 4-inch stockinette is appropriate for most patients, but 3-inch stockinette may be needed for smaller patients
- Cast padding: 3- or 4-inch rolls (depending on patient size), soft cotton (e.g., Webril) or synthetic (e.g., polyester)
- Synthetic waterproof cast liner (e.g., Gore Procel, Scotchcast Wet or Dry, Delta-Dry, Waterpruf) (optional)
- Cast material: 3- or 4-inch rolls, depending on patient size, plaster or synthetic (e.g., fiberglass)

**Figure 186-1** Materials needed for casting: cast padding, casting material, cast spreader, cast cutter, and stockinette.

- Rubber heels (for walking cast, but may not be needed for fiberglass cast)
- Gloves, nonsterile
- Gown and shoe covers for the clinician
- Patient towels or drapes
- Water bucket with tepid water (if using plaster, should have traps in drains)
- Chinese finger traps
- Foot stand (optional)
- Scissors
- Cast cutter
- Cast spreader
- See Chapter 187, Cast Immobilization and Upper Extremity Splinting, if cast removal protective strips (e.g., De-Flex) indicated or desired to protect skin from cast saw during removal

# **Splinting**

- Most of foregoing supplies for casting or premade splint material (plaster or synthetic)
- Compression wrap elastic bandage (Ace bandage)

#### **Taping for Ankle**

- Skin preparation (benzoin)
- Lubricant (optional)

**NOTE:** The lubricant may be applied to the skin at sites of potential friction or irritation.

- Underwrap
- 1½- or 2-inch athletic tape
- Pressure pads or moleskin

# **Taping for Plantar Fasciitis**

Equipment is similar to that used for the McConnell method of taping for patellofemoral knee pain:

- 2-inch dressing retention sheet (skin tape, white)
- 1½-inch patellofemoral adhesive tape (high-tensile strength tape, brown; some of the original work with McConnell taping was rumored to have used duct tape!)
- Alcohol swabs
- Commercial adhesive remover

# PREPROCEDURE PATIENT PREPARATION

Obtain verbal or written consent. Possible complications should be explained to the patient. For example, the patient should be aware that there will be a temporary loss of flexibility following immobilization, especially in the foot. In some cases, a partial loss of flexibility following immobilization.

ity can become permanent. Place the patient in a seated or supine position. Some clinicians prefer a prone position with the knee flexed 90 degrees.

# **TECHNIQUE**

#### **Splinting**

Most clinicians have access to premade splinting materials that are fixed or inflatable (e.g., Aircast). However, inexpensive splints can be made from a plaster cast roll and cast padding:

- 1. Estimate the length of the splint you plan to use.
- 2. Unroll cast material into layers, making 11 to 13 layers.
- 3. In a similar fashion, unroll cast padding into layers, making 6 to 8 layers.
- 4. Unroll a single layer of cast padding for the outside of the splint.
- 5. The plaster cast material will be placed between the inner and outer layers of cast padding. The inner layers (6 to 8 layers) are placed between the splint and the skin, while the single outer layer of cast padding is placed on the outside of the splint. The latter is used to prevent the Ace bandage from adhering to the plaster.

Generally, when making a splint from casting materials, plaster is used. With this type of splint, the padding will not be wet. The casting material is immersed in water separately. Premade splints may be plaster or fiberglass. With premade materials, the padding will be wet. Premade splint material can also be simulated by rolling a stockinette over the outside of the 11 to 13 layers of cast materials. Fold over the ends of the stockinette and tape them to keep the splint neat. Both the stockinette and the casting materials are then immersed in water together. Both will be wet when applying. Several layers of cast padding are then placed between the patient's skin and this splint to prevent skin breakdown.

Two types of ankle splints will be discussed: sugar tong and posterior. Application depends on the indication and degree of stabilization desired. The sugar-tong (stirrup) splint may be used in ankle sprains to prevent inversion or eversion.

# Sugar-Tong (Stirrup) Splint

- Measure from the fibular head (at the knee) to the calcaneus, double that measurement, and cut the splint material and padding to size.
- Wet the splint material and remove excess water by applying gentle pressure across the width of the splint material.
- Place the padding against the patient's skin and have the patient or an assistant hold it in place.
- 4. Apply the splint material against the lateral aspect of the leg, starting just distal to the fibular head (2 fingerbreadths below). Wrap the splint under the heel, and return it up the medial side of the leg to just below the knee (Fig. 186-2). (It is U-shaped like a long sugar tong; the anterior and posterior aspects are open.)
- 5. Mold the splint material to support the ankle and heel.
- 6. Place a layer of padding over the splint.
- 7. Wrap the splint material to hold it in place with an elastic bandage or a roll of cast padding (Fig. 186-3).

# Posterior Splint

The posterior splint may be used with stable tibial or fibular fractures and plantar fasciitis to restrict dorsiflexion or plantar flexion of the foot and ankle complex.

- Measure from the metatarsal heads to just distal to the popliteal fossa (2 fingerbreaths above), and cut the splint material and padding to size.
- 2. Wet the splint material and remove excess water.
- 3. Place the padding against the patient's skin and have the patient or an assistant hold it in place.

**Figure 186-2** Splint material in the shape of a U (sugar tong). The splint allows for swelling while providing medial and lateral support.

- 4. Apply the splint material over the padding and against the plantar aspect of the foot and along the posterior aspect of the leg. Extend the splint from the metatarsal heads to just distal to the popliteal fossa (Fig. 186-4).
- 5. Mold the splint material to support the ankle and heel.
- 6. Place a layer of padding over the outside of the splint.
- 7. Wrap the splint material to hold it in place with an elastic bandage or a roll of cast padding (Fig. 186-5).

#### **Casting**

#### **Short-Leg Cast**

A short-leg cast may be used for stable tibial or fibular fractures, fifth metatarsal fractures, or severe ankle sprains (after acute swelling subsides).

- Measure from the metatarsal heads to the knee and cut the stockinette to length. Be sure to allow extra stockinette to fold over the ends of the cast.
- Slide stockinette on and smooth all wrinkles or folds. The crease that will be formed at the anterior ankle should be trimmed away (Fig. 186-6).

**Figure 186-3** Finished sugar-tong splint held in place with a compression wrap.

**Figure 186-4** Cast material runs along the posterior aspect of the lower leg and the plantar surface, providing immobilization for ankle dorsiflexion and plantar flexion.

- 3. Place the ankle in neutral position (90 degrees). Failure to flex it to 90 degrees may lead to difficulty in ambulating and to Achilles tendon shortening. A foot stand may be useful to support the foot.
- 4. Wrap the cast padding over the stockinette, starting at the foot. The padding should overlap 50% with each consecutive wrap. The padding should extend from the metatarsal heads to just distal to the fibular head. Care should be taken to provide adequate padding around the heel, the malleoli, the metatarsal heads, the proximal fibula, and the anterior tibia (Fig. 186-7).
- 5. Wet the cast material. Wrap the foot and ankle with the cast material in a manner similar to that already done with the cast padding. It should be wrapped over the cast padding. Maintain moderate tension, and overlap the rolls by 50% (Fig. 186-8).
- 6. Mold the cast to ensure neutral position of the ankle at 90 degrees.
- 7. Fold the stockinette over the ends of the cast to provide a smooth edge (Fig. 186-9).
- 8. Apply a final layer of cast material over the initial layer and the folded-down edge of the stockinette at the ends (Fig. 186-10). For a walking cast, 6 to 8 layers of reinforcing strips may be placed under the heel and foot prior to the final cast layer.

**Figure 186-5** Finished posterior splint held in place with a compression wrap.

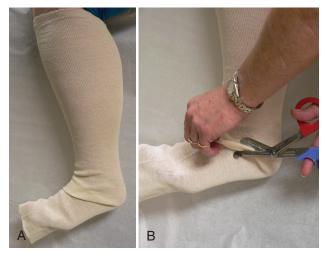

Figure 186-6 A, Stockinette is placed on the lower leg from the knee to the toes. B, The transverse crease formed at the ankle should be removed.

Figure 186-7 Cast padding is applied with 50% overlap on each turn.

Figure 186-8 Application of cast material with 50% overlap on each turn.

Figure 186-9 After the first roll of cast material is placed, the stockinette is folded back over the ends.

These are shaped like an L and go from the metatarsal heads to the midcalf to provide additional support.

- 9. Allow 10 minutes for the cast to set, and instruct the patient not to bear weight for at least 24 hours. Provide crutches for ambulation.
- 10. A walking boot may be fitted to ease ambulation. Again, wait 24 hours for the cast to set before allowing weight bearing. A cast check by the clinician the next day can assure a proper fit.

NOTE: A walking heel is unnecessary for a fiberglass cast.

#### Cast Removal or Bivalving

- 1. When splitting the cast, both the medial and lateral sides should be cut.
- 2. Starting at the top of the cast, make straight cuts that run posterior to the malleoli. Use a finger to stabilize the saw against the cast and to control the depth of the cut.

NOTE: When using a cast saw, make plunging cuts along the length of the cut. Do not attempt to steadily drag the saw along the length of the cut, as this will cause the blade to heat up, and may burn the patient.

3. Next, make cuts along the medial and lateral sides of the foot that intersect with the initial cuts. Take care to avoid cutting over bony prominences (Fig. 186-11).

Figure 186-10 Finished short-leg cast.

**Figure 186-11** When a cast is being removed, medial and lateral cuts are made posterior to the malleoli.

- 4. After the cuts are complete, a cast spreader is inserted into the cut and spread to widen the cut.
- The cast padding and stockinette are then cut with blunt-tipped scissors.
- 6. The cast may then be opened and removed, or wrapped with a compression bandage to serve as a splint.

**NOTE:** When wrapped with a compression bandage, the resultant splint provides almost as much support as a cast; therefore a clinician should have a low threshold for bivalving a cast to minimize complications. The same saws can be used for both plaster and fiberglass.

# **Bracing**

Ankle bracing may be used prophylactically (to prevent injury), therapeutically, after an acute injury, or after injury to prevent reinjury. Commercial premade braces come in several styles. All styles may be used for any of these indications. Consider patient comfort and stability in choosing a brace. If the patient does not tolerate one style, consider a different one. Available styles include a lace-up, stirrup, or hinged brace.

#### **Taping**

#### **Plantar Fasciitis**

For this procedure, two pieces of skin tape will be applied followed by two pieces of high-tensile adhesive tape placed over them. The first three pieces of tape are simply applied smoothly and without wrinkles or any tension; the last piece of tape is the only one applied under tension.

**SKIN PREPARATION.** With the patient sitting on an examination table, skin oils and other debris should be cleansed from the plantar aspect of the affected foot with alcohol. While the alcohol is allowed to dry, palpate the dorsalis pedis pulse. Document the presence or absence of the pulse.

#### APPLICATION

- 1. Place the foot in a neutral position (90 degrees), approximately the same position as if the patient were standing on it. From this position, it should be slightly inverted or "turned in" (sole of the foot facing slightly medially).
- 2. Apply skin tape (white tape) from the ball of the foot (Fig. 186-12A) to the middle of the heel (Fig. 186-12B). The upper edge of the tape will extend slightly up the medial side of the foot, but it should not be higher than one third of the way up to the medial malleolus. In fact, keeping it low on the foot and simply taping around the posterior calcaneus may minimize any friction on the Achilles tendon. Smooth the wrinkles and bubbles; there should be no tension applied to this piece of tape.
- 3. Locate the navicular bone. It causes the bony projection about 1 inch anterior to the medial malleolus. Apply skin tape (white tape), under no tension, from the heel (Fig. 186-12C) up the medial aspect of the foot to end on top of the foot (Fig. 186-12D). This tape should cover and include the navicular bone and extend past the midline of the dorsum of the foot.
- 4. Apply tensile tape (brown tape) of the same length in the same location and manner as the first piece of skin tape, simply covering that skin tape. Smooth any wrinkles or bubbles, but do not apply any tension.
- 5. Apply a second piece of tensile tape (brown tape) over the second piece of skin tape. This tape should be applied under tension, but not so much as to occlude the dorsalis pedis pulse.
- When the patient stands, he or she should be almost symptom free because the tape bears the weight of the plantar fascia. For severe cases of plantar fasciitis, adding a slight degree of plantar

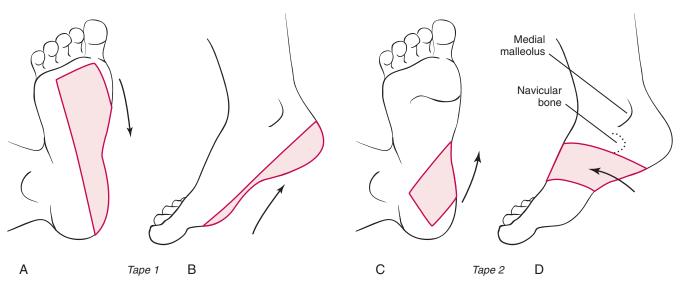

Figure 186-12 Skin tape I (white tape) is applied from the ball of the foot (**A**) to the middle of the heel (**B**). Skin tape 2 (white tape) is applied from the heel (**C**) up the medial aspect of the foot to end on top of the foot (**D**). Tensile tape pieces I and 2 are applied in the same locations and directions. They should be the same lengths as the skin tape.

flexion to the foot prior to taping, in addition to the slight inversion, will take the weight off the fascia even more.

- 7. Because it loses strength with weight bearing, the tape should be removed and reapplied daily for 4 to 6 weeks. Outlining the outside edges of the tape with a permanent marker may be helpful for patient education purposes. This outline may help them when reapplying the tape the next day. They may want to outline it each day or use a copy of Figure 186-12 to remind them of how to reapply the tape. When the tape is being changed, the foot should be massaged and put through range-of-motion exercises. Using a commercial adhesive remover will help remove the debris from the prior day's skin tape.
- 8. For more severe cases, if the patient is symptomatic when bearing weight following taping, gradually more degrees of plantar flexion should be applied with each day of subsequent taping. The goal should be to bear weight with almost no symptoms for 4 to 6 weeks. This allows the fascia to heal.
- 9. Following resolution of symptoms and completion of the taping regimen, the foot should be rehabilitated aggressively with stretching and range-of-motion exercises.

**NOTE:** One of the success stories of the physical therapists that first utilized this technique was a woman who had had plantar fasciitis for 7 years!

#### **Ankle**

**SKIN PREPARATION.** Ankle taping provides the greatest support when applied directly against the skin. Daily application, however, will likely cause skin irritation. The use of underwrap material can prevent this. Shave the foot and ankle. Apply a coating of skin preparation, usually benzoin, to protect the skin and provide better adhesion. Avoid the use of skin preparation in patients with a history of sensitivity or allergy to these products (underwrap is recommended in these patients [Fig. 186-13A]). Lubrication or padding may be applied to the skin at sites of potential friction or irritation (Fig. 186-13B).

**APPLICATION.** Several methods can be used for taping the ankle. The most commonly used is the *closed basket-weave technique*, also known as the Gibney technique, which provides strong tape support (see Fig. 186-13). This extra support may be needed in either recently sprained or chronically weak ankles.

- 1. An anchor strip is placed around the ankle 5 to 6 inches above the malleoli (Fig. 186-13C).
- 2. A second anchor strip is placed around the instep.
- 3. A stirrup strip is placed posterior to the malleoli (Fig. 186-13D). For an inversion injury, hold the foot in *eversion* when applying the stirrup strips. Conversely, hold the foot in *inversion* for an eversion injury.
- 4. The first horizontal (Gibney) strip is placed under the malleoli, and attached to the foot anchor (Fig. 186-13D).
- 5. A second stirrup is placed overlapping the first by 50%, followed by a second Gibney strip, also overlapping the first by 50%. A third stirrup and Gibney are then placed in similar fashion (Fig. 186-13E).
- 6. Placement of the Gibney strips is then continued up the ankle to the anchor strip (Fig. 186-13F).
- 7. Two or three strips are placed around the arch for added support (Fig. 186-13G).
- 8. Lastly, heel locks are applied as a final support. Starting high on the instep, wrap the tape posteriorly across the Achilles tendon, downward, hooking the heel. It should then lead under the arch and up the opposite side to finish at the starting point. The heel lock is completed by repeating the wrap in the opposite direction (Fig. 186-13H).

An alternative method, the *open basket-weave technique*, allows for some degree of dorsiflexion and plantar flexion. This technique accommodates swelling and may be used after acute injury. The

procedure for the open basket weave is the same as for the closed basket weave, with the notable exception of the Gibney strip placement. The Gibney strips are placed with a gap anteriorly. After the Gibney strips are placed, the gap is closed and the ends are locked by two to four strips running down the instep.

#### **COMPLICATIONS**

- Nerve entrapment: When casting, compression of the common peroneal nerve at the fibular head may lead to foot drop. Correct placement of the proximal end of the cast is essential.
- Compartment syndrome: This may be seen in patients with injuries due to high-velocity forces (e.g., motor vehicle accidents) or by applying the cast before swelling has reached its maximum. If the patient notes any pain caused by the cast, pain out of proportion to the injury, pain not controlled with oral analgesics, or progressively increasing pain, the cast should be bivalved or removed immediately to check compartment pressures (see Chapter 188, Compartment Syndrome Evaluation) and to evaluate for any neurovascular compromise. Treatment of the fracture or maintenance of reduction of the fracture is always a second priority to preserving the blood supply to the soft tissue and bone.

**NOTE:** One of the earliest signs of an impending compartment syndrome is pain on resisted plantar flexion of the great toe. Have the patient dorsiflex his or her toe, and if pain radiates into the leg when the clinician attempts to plantarflex the toe, the cast should be bivalved or removed immediately.

- Loosening of the cast: Application of a cast when swelling is present may lead to cast looseness when the swelling abates. A loose cast will no longer provide adequate stability and immobilization
- Skin necrosis: Skin necrosis may be caused by pressure over bony prominences. This is best prevented by placing extra padding at potential pressure points (Fig. 186-14). If necessary, a window may be cut in the cast to remove the source of irritation. A window should not be cut, however, in areas that have acute swelling. In that case, a different form of immobilization should be employed.
- Delayed union, nonunion, atrophic or hypertrophic union, or malunion: All are possible complications of fractures. Inadequate assessment of the initial radiographs, improper management of the fracture (including incomplete reduction), poor patient adherence and compliance, increased age, medications, and presence of osteopenia or osteoporosis are all possibly causes of these complications. Smoking or taking anti-inflammatory medications delays the healing time and increases the risk for improper fracture healing, especially in weight-bearing bones such as the ankle, foot, or calcaneous. If the patient smokes, the fracture healing time in the ankle is doubled compared to a nonsmoker.
- Joint stiffness: Patients often suffer from joint stiffness as a result
  of immobilization. This is best prevented by not immobilizing
  joints any longer than what is needed for fracture healing.

#### POSTPROCEDURE PATIENT EDUCATION

In an acute injury, after immobilization the patient should elevate the leg for 48 to 72 hours to prevent swelling. Ice can be used, in a sealed container, over the cast or splint to help alleviate pain. If a non-waterproof cast or splint is used, every effort should be made to keep the cast or splint dry. Patients should remove or cover it when bathing. If a non-waterproof cast or splint does become wet, patients may dry it with a hair dryer set on the cool setting.

Nothing should be inserted between a cast and the skin. This may cause abrasions and undetected infections. With a cast, patients should call immediately if they notice pain, fever, tightness or irritation, numbness, or discolored or cool toes.

Figure 186-13 Closed basket-weave (Gibney) technique. A, Application of thin underwrap tape. B, Application of padding at pressure points. C, Anchor straps are placed either directly onto skin or over underwrap. **D**, Application of first stirrup and Gibney strips. E, Stirrup and Gibney strips are applied in an alternating fashion. F, Gibney strips are continued up the ankle to the anchor strip. G, Application of arch strips. H, Heel locks are applied for additional support.

# **CPT/BILLING CODES**

# Fracture Management

Fracture care CPT codes include initial management of fractures, along with initial splint or cast application. These codes include subsequent routine cast care and removal.

Codes for closed treatment without manipulation include the following:

27750 Tibial shaft fracture 27760 Medial malleolus fracture

Proximal fibula or fibular shaft fracture 27780 Distal fibular (lateral malleolus) fracture

Codes for closed treatment with manipulation include the following:

- Tibial shaft fracture 27752
- 27762 Medial malleolus fracture
- Proximal fibula or fibular shaft fracture 27781
- 27788 Distal fibular (lateral malleolus) fracture

Figure 186-14 Common locations for pressure sores are noted on the cast. Note the outline of the fibular head above the cast. This is the site of possible peroneal nerve entrapment.

# **Cast or Splint Application**

The following codes can be used when not part of comprehensive fracture management, or when used for soft tissue injuries. If a cast needs replacement, these codes can also be used.

	_
29405	Application of short-leg cast (below knee to toes)
29425	Walking or ambulatory type
29440	Adding walker to previously applied cast
29515	Application of short-leg splint (calf to foot)
29540	Strapping; ankle and/or foot
29700	Removal or bivalving of short-leg cast applied by another
	physician
29705	Removal or bivalving of full-leg cast applied by another
	physician
29730	Windowing of cast applied by another physician
29740	Wedging of cast applied by another physician
29799	Unlisted procedure, casting or strapping
_	<b>1</b>

# CAST IMMOBILIZATION AND UPPER EXTREMITY SPLINTING

Scott W. Eathorne • Todd M. Sheperd

Cast immobilization is a technique used to treat a variety of medical conditions encountered by the primary care clinician. Although newer technologies have led to an evolution in casting materials, the general principles of this valuable technique have stood the test of time. By having knowledge of the materials available and an understanding of the indications and fundamental precepts of cast immobilization, and by developing the necessary manual or dexterity skills, the primary care clinician can easily treat the patient who has an injury amenable to such therapy.

In the upper extremity, splints made from casting material (e.g., thumb spica, sugar-tong) are occasionally used in place of circumferential casts. Some of these will be covered in this chapter. Please note that splinting and casting in the lower extremity are also discussed in Chapter 186, Ankle and Foot Splinting, Casting, and Taping.

# **HISTORY**

The use of immobilization to treat acute fractures dates back to the era of the Fifth Dynasty of Egypt (2498–2345 BCE) when bark was used to splint fractures of the forearm. Gypsum, from which plaster of Paris is derived, was initially used around the sixteenth century in parts of the Ottoman Empire. With the development, in 1927, of the hard-coated plaster of Paris rolls, a binder was incorporated that improved the adherence of the plaster to the cloth. Since then, various additives have been used to either accelerate (salicylic acid, zinc, or aluminum) or slow down (gums or glue) the setting process.

Currently, fiberglass is the most common material used in casting. It has the advantages of being stronger and lighter (approximately two to three times stronger for any given thickness) than plaster, and it creates less heat during application. However, it is more difficult to mold. The cost of fiberglass continues to be more than that of plaster, but in recent years this difference has decreased significantly. In addition to newer casting materials, the development of synthetic padding (Gore-Tex) has allowed most casts to survive significant exposure to water without damage.

#### **INDICATIONS**

- A variety of stable, acute fractures
- Dislocations that have been reduced
- Injuries to the soft tissues, including muscle, tendon, and ligament
- Congenital and acquired deformities (e.g., correction of talipes equinovarus, congenital clubfoot)
- For the stabilization and protection of vascular, tendon, and nerve injuries following surgical repair

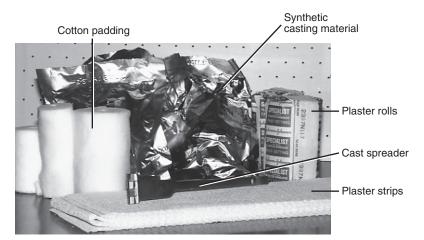

The most common diagnosis for which the primary care clinician uses cast immobilization is the stable, nondisplaced, closed fracture of a long bone. The primary care clinician often treats fractures involving the radius or ulna, phalanges, metacarpals, metatarsals, and malleoli. (See Chapter 190, Fracture Care.) Other conditions include certain grade III ligament sprains (e.g., ankle), Achilles tendon disruptions, and tendonitis refractory to other forms of therapy.

# **CAST APPLICATION EQUIPMENT**

- Rubber gloves
- Gown and shoe covers for the clinician
- Patient towels or drapes
- Stockinette (2-, 3-, and 4-inch widths)
- Felt padding, soft cotton (e.g., Webril), or synthetic (e.g., polyester) bandages (2-, 3-, 4-, and 6-inch widths)
- Synthetic waterproof cast liner (e.g., Gore Procel, Scotchcast Wet or Dry, Delta-Dry, Waterpruf)
- Rubber heels (walking cast)
- Cast removal protective strip (e.g., De-Flex) to eventually protect skin from cast saw
- Casting material (Fig. 187-1)
  - Plaster (e.g., plaster of Paris, avoid thicker than 10 ply, which can cause thermal injury to patient)
  - Synthetic (e.g., fiberglass)
- Water source (if using plaster, should have traps in drains and water temperature less than 24° C/75° F)
- Elastic (e.g., Ace) bandages (2-, 3-, 4-, and 6-inch widths)
- Slings
- Scissors
- Chinese finger traps
- Leg stand

When water is added to the plaster, the water molecules are incorporated into the calcium sulfate hemihydrate (i.e., plaster of Paris) molecules with a resultant exothermic reaction. The powdery white substance is converted into a solid, rock-hard material, and a significant amount of heat is generated. A curing process then follows over the next few days, characterized by continued water evaporation; this process is accelerated by low humidity, high ambient temperature, and increased air circulation.

Synthetic materials require immersion in water to activate the curing process, with generally less heat generated than plaster. Attention to water temperature in this process is especially important, because water that is too warm (>24° C/75° F) can lead to rapid curing and significant difficulty in application. Water at higher than these temperatures or plaster of Paris thicker than 10 ply can also result in thermal injury to the patient.

**Figure 187-1** Materials needed for casting: cotton padding, synthetic casting material or plaster rolls, cast spreader, cast cutter (not shown), and plaster strips.

Advantages of plaster casts over fiberglass include low cost, ease of molding, long shelf-life, and low allergenicity. Synthetic cast material is more expensive, but this margin has narrowed in the years since fiberglass was introduced. Fiberglass has also improved in its ease of application and continues to be superior in strength, durability, weight, water resistance, and drying time. Both materials are available in multiple sizes, ranging from 2 to 5 inches in width for general, circumferential cast use.

Ideally, a single room or area in the clinic, emergency department, or hospital should be dedicated to the application of casts and splints. This room should have a plaster trap in the sink, and all materials should be easily available. Rubber gloves, gowns, shoe covers, and towels or drapes should be available to protect both the clinician and patient from the inevitable exposure to casting materials. An easily cleaned examination table, stool, and leg stand can greatly facilitate the process of cast application.

#### **COMMON CAST TYPES**

See Chapter 190, Fracture Care.

#### **Short-Arm Casts**

Short-arm casts are generally indicated in the treatment of stable sprains of the wrist, as well as some stable fractures of the distal radius, ulna, carpal bones, and metacarpals. Clinicians performing cast immobilization should be aware of those fractures requiring orthopedic evaluation for possible open reduction and internal fixation. Materials required for short-arm cast applications include a 3-inch stockinette, two rolls of 3-inch cast padding (the waterproof liner replaces the need for both stockinette and padding), and two to four rolls of either 3- or 4-inch plaster bandage (or 2- or 3-inch fiberglass bandage). In general, adult males will require 4-inch plaster (3-inch fiberglass) and children will require 3-inch plaster (2-inch fiberglass). Adolescents and females may require either size depending on preference and size of extremity. The patient should be supine or seated, with the arm abducted 90 degrees and the elbow flexed 90 degrees. The wrist should be slightly extended and in a position of function (Fig. 187-2). Chinese finger traps attached to the patient and suspended from above can support the arm and assist

Figure 187-2 Position of the wrist in the application of arm casts.

in maintaining the position of function. The cast extends from the proximal forearm (approximately 1 inch distal to the flexion crease of the elbow) distally to include the palm and dorsum of the hand, completely covering the forearm. The metacarpal-phalangeal (MCP) joints are allowed complete motion, with the cast stopping just proximal to the distal palmar crease (Fig. 187-3). Extra padding should be applied over the ulnar styloid. Short-arm casts only partially immobilize the wrist joint and allow movement of the thumb, including opposition with the fifth digit. In addition, they allow for supination and pronation to occur because the elbow is not included. An adaptation of the short-arm cast is the *short-arm thumb spica*, in which the thumb is included to the level of the interphalangeal (IP) joint (Fig. 187-4). This type of cast may be used for injuries to the scaphoid, trapezium, or first metacarpal, or for any injury requiring wrist and thumb immobilization.

# Long-Arm Casts

Long-arm casts can be fashioned by extending a short-arm cast proximally, with the elbow maintained in 90 degrees of flexion. The padding and plaster should be extended to the proximal humerus, ending 2 to 3 fingerbreadths below the axilla. Be careful to provide extra padding over the pressure point at the olecranon. Plenty of padding should also be placed over the proximal end of the cast or the patient will complain of the sharp edges.

# **Short-Leg Casts**

Short-leg casts are generally indicated in the treatment of some stable ligamentous injuries to the ankle, and stable fractures of the ankle, calcaneus, tarsals, and metatarsals. Materials include a 4-inch stockinette and three rolls of 4-inch cast padding (or water-proof liner). Use of fiberglass is generally preferred in these casts because of its increased durability. With fiberglass casts, three rolls of 4-inch fiberglass bandage are generally needed. An extra reinforcing strip of heavy-duty fiberglass can also be used posteriorly along

**Figure 187-3** Appearance of a completed short-arm cast. Note that the thumb and fingers are free to move.

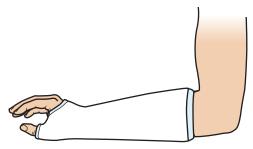

Figure 187-4 Short-arm cast with thumb spica.

the bottom of the foot up the back of the leg. For plaster casts (used less often), materials vary widely based on personal preference, but they usually include two to three rolls of 6-inch plaster bandage and an adequate number of plaster splint strips (again for posterior and foot reinforcement), with size based on patient limb size. Application of the short-leg cast is achieved either in the sitting position, with the leg hanging over the table, or prone, with the knee flexed to 90 degrees to help relax the gastrocnemius muscle. The ankle is usually held at a 90-degree angle to the leg, but this angle may be altered depending on the type of injury. A foot-stand or assistant can provide support to the foot. The cast extends from just below the knee joint, usually including the fibular head, distally to the base of the toes, including the metatarsal heads (Fig. 187-5). Again, the ankle joint is only partially immobilized, since the cast does not involve both the joint above and below. For walking short-leg casts (Fig. 187-6), a posterior reinforcing strip is placed and molded after application of the second roll of fiberglass bandage and before placing the final roll. The walker can be applied the same day or at a later time. If applied initially, patients have a tendency to walk on it before the primary cast is dry enough, leading to breakdown of the cast.

**Figure 187-5** Appearance of a completed short-leg cast. The cast should hold the ankle at 90 degrees. In addition, the proximal end of the cast should be far enough from the knee to eliminate the possibility of skin irritation with knee flexion.

Figure 187-6 Short-leg cast with walker.

# Long-Leg Casts

Long-leg casts can be fashioned by extending a short-leg cast proximally up to the groin. The padding and plaster should be extended to the proximal femur, ending several fingerbreadths below the groin. The knee is in slight flexion and the foot is at 90 degrees. There should be no internal or external rotation of the foot. The knee should be supported in this slight flexion while the cast sets. To maintain strength, make sure there is adequate overlap of the casting material when extending proximally from the knee. In addition, make sure extra padding is provided over the pressure point at the anterior patella. Plenty of padding should also be placed over the proximal end of the cast or the patient will complain of the sharp edges.

# **Other Casts and Splints**

Other types of common casts and splints are shown in Figure 187-7. Even with splints, where casting materials do not totally surround the extremity, there is generally a layer of stockinette around the entire area followed by the padding, then the casting material. The casting material is held in place with an Ace wrap or similar material.

# PREPROCEDURE PATIENT PREPARATION

After diagnosing an injury requiring cast immobilization, and before application of the cast, the indications for casting, estimated duration of immobilization, and potential impact on activities of daily living should be discussed with the patient. Typically, discussion of common problems and potential complications from casting occur following application. Online references for patient education handouts can be found at the end of this chapter (www.expertconsult.com). If there is a chance that the cost of synthetic material will not be covered by the patient's insurance, this should be discussed prior to its use.

# **TECHNIQUE**

Casts are generally applied to immobilize and protect an injured part of the body in a position that will facilitate healing. Three-point contact and stabilization are necessary to maintain most closed reductions. The following simple principles direct the fundamentals of cast immobilization. First, to best approach complete immobilization, a cast must conform precisely to the anatomy of the region being immobilized. Failure to accomplish this can lead to unacceptable movement of the injured area, leading to potential loss of reduction, malalignment of a reduced dislocation, or persistent inflammation in a refractory tendonitis. Second, effective immobilization is achieved only by including a sufficient amount of injured area in the cast. Ideally, this is accomplished by including the joint above and below the area of injury. However, exceptions to this rule are made based on the nature of the injury. Achieving adequate immobilization requires attention to these fundamentals before application of the cast. If

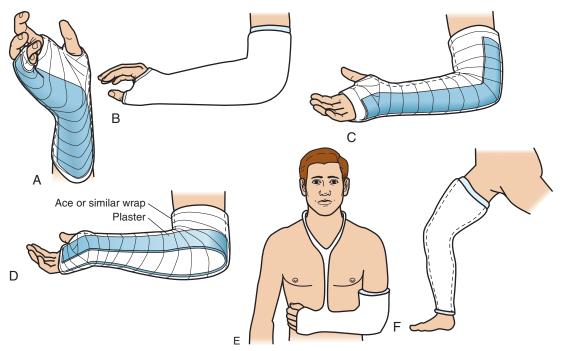

Figure 187-7 Common casts and splints. **A,** Ulnar gutter splint is used to immobilize fractures and serious soft tissue injuries of the ring and little fingers and fractures of the neck, shaft, and base of the fourth and fifth metacarpals. **B,** Long-arm cast with thumb spica is used to treat navicular fractures, complicated Colles' fractures, and nondisplaced radius and ulnar shaft fractures. **C,** Long-arm posterior splint is used for severe lateral epicondylitis and elbow dislocation. **D,** Sugar-tong splint is used for fractures of the distal radius and ulna. **E,** Long-arm hanging cast. **F,** Long-leg cast is used for fractures such as patellar, uncomplicated tibial plateau, and minimally displaced tibial/fibular shaft fractures as well as for medial collateral ligament or lateral collateral ligament avulsion and nondisplaced osteochondritis.

these goals cannot be met, the injury may best be served by another means of immobilization.

- 1. Before application of any casting materials, cleanse, dry, and thoroughly inspect the skin to be included in the cast for any lesions such as lacerations, abrasions, and ulcers. If present, they should be noted and, if significant, may contraindicate inclusion in the cast or may require special "window" techniques. Depending on the acuity of the injury and degree of soft tissue swelling, immobilization using circumferential casting may be contraindicated. In this situation, the injury may require the use of a splint for immobilization until the swelling has diminished.
- After this assessment is completed, position the patient so that the injured area can be held most easily in the desired position throughout the application process. This positioning often requires the use of an assistant or assistive device (e.g., leg stand, finger traps).

**NOTE:** Cast application is performed in a step-wise manner, and development of a systematic approach will help ensure consistency and minimize the potential for error.

- 3. The *first layer* generally applied in casting is the *stockinette*. A poorly fitting stockinette can contribute to skin breakdown, so it must be applied carefully. Use a 3-inch-wide stockinette for adult arm casts, and a 4-inch-wide for legs, with exceptions based on the extremes of limb size. The material should go well past the toes or fingertips and 4 to 5 inches above the elbow or knee (Fig. 187-8A). (Cutting the stockinette too short is a common problem among those learning the procedure.) Some of this "extra" material is ultimately incorporated into the cast or, eventually, cut off.
- 4. Remove all transverse wrinkles; they become pressure points after cast application and can cause skin breakdown. This can be achieved by cutting the redundant material, which is usually at a joint. Figure 187-8B shows a short-leg stockinette that has been cut and then overlaid at the anterior ankle to reduce wrinkles.

5. After ensuring that the stockinette overlying the area is smooth and free of wrinkles, apply the second layer. The second layer consists of soft cast padding material (Webril), which comes in rolls and is applied in a circular manner. Start at one end (usually distal) and work toward the other; on the first turn around the extremity, roll the padding over itself to create an anchor. After this, each subsequent turn will overlap itself by 50% (Fig. 187-9).

**Figure 187-8 A,** Demonstration of proper stockinette application for short-arm cast. Enough excess is present to allow a cuff to be created below the final layer of casting material. **B,** Application of stockinette for a short-leg cast, demonstrating the technique to eliminate transverse wrinkle at ankle. Note the length of the stockinette for a short-leg cast.

**Figure 187-9** Application of soft cast padding. Beginning at one end, cast padding is added while overlapping each turn by half. (From Mercier LR: Practical Orthopedics, 5th ed. St Louis, Mosby, 2000.)

**Figure 187-10** Short-arm cast after application of cast padding and before addition of casting material.

- Two layers of cast padding can be applied, but care should be taken not to pad too much because this can lead to a loose cast. The goal with padding, as with the stockinette, is to avoid wrinkles, which may contribute to pressure points. Stretch or tear the advancing edge that is to encircle a larger portion of the extremity in order to avoid wrinkles. Keeping in mind the local anatomy, apply additional padding to bony prominences and likely areas of increased local pressure (e.g., flexion creases; fulcrum points such as the proximal anterior tibia where short-leg walking casts may rub; and common areas of nerve compression or pressure necrosis, such as over the proximal fibula). Felt pads appropriately fashioned can prevent common complications and improve comfort. Figure 187-10 shows a short-arm cast after cast padding application and before application of cast material. Although padding is important, excess padding over bony prominences can also lead to excess pressure; therefore, it should be avoided.
- When using the waterproof cast liner, it is applied in a manner identical to the application of cast padding and eliminates the need for stockinette use. By using this material, only two total layers of material are needed (cast liner and cast material). To apply, start unrolling onto the extremity from either the distal or proximal end. Remember to keep the adhesive side of the cast liner away from the patient's skin. The material is applied until the opposite end of the desired endpoint is reached and is extended 4 to 5 cm beyond the desired length of the cast. The excess will allow the ends to be folded back at the margins before casting material application (Fig. 187-11A). Apply additional material to bony prominences to prevent pressure-related complications. Unlike traditional cast padding, the waterproof cast liner must be cut to achieve proper sizing because it does not tear (Fig. 187-11B and C). In addition, because fewer layers of padding are used, waterproof cast liner requires the use of a protective strip below the cast material (Fig. 187-11D) to protect from the cast saw.
- 7. A protective strip can be placed under any cast to minimize the risk of thermal injury or damage to the skin with later use of the cast saw to remove the cast. Many experts will extend the strip an inch or so beyond the anticipated margin of the cast, far enough to enfold it into the end or cuff of the cast, right over the stockinette. This simplifies locating and following the strip

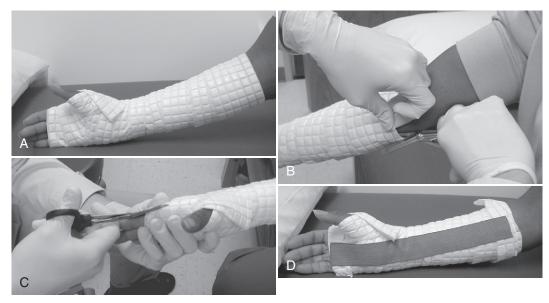

Figure 187-11 Gore-Tex application. **A,** Gore-Tex liner applied 4 to 5 cm beyond desired cast length. **B** and **C,** Using scissors to cut material and allow liner to be folded. **D,** Protective strip applied before application of cast materials. Extend the strip beyond the anticipated margin of the casting material.

- when later using the cast saw, especially if the strip is extended into both the proximal and distal cuffs of the cast. The resistance of the strip to being cut by the saw is compromised over hard, bony surfaces; therefore, use over bony prominences should be avoided.
- 8. Apply the third layer (or second layer if cast liner was used), which consists of the cast material itself. The type of material used (plaster versus synthetic) dictates how the next step will be completed. Although application is quite similar, a few significant differences are worth noting. When using plaster-impregnated rolls, place each roll individually in water at room temperature and submerse until the bubbling stops. Cold water slows the setting process, whereas warmer water speeds it. A faster setting may be desirable when immobilizing a recently reduced dislocation. After removing from the water, gently squeeze and twist the roll to eliminate excess water and begin the application (Fig. 187-12A). Placement of the plaster rolls should follow the direction of the cast padding and should be applied in a similar manner. The first turn has 100% overlap, and each additional turn overlaps approximately 50%. To avoid transverse wrinkles, plaster rolls can be tucked (folded over) at the edges when redundancy occurs and smoothed with the palm of the hand (Fig. 187-12B and C). Avoid stretching and applying undue pressure with each turn. Apply four to six layers of plaster evenly, with extra reinforcement in areas under increased stress. Apply each roll in a consistent manner, either distal-to-proximal or proximal-to-distal, with the length of the area to be immobilized covered with each layer. Covering only a portion of the extremity with one roll and overlapping with the next roll may lead to inherent weakness and future difficulties with the cast. Before placing the final layers, the ends of the stockinette should be folded over onto the initial layers. Reinforcing strips or cast cushions, if used, should be added now (depending on the type of cast being applied; Fig. 187-12D).
- 9. Place the final layers of cast material and smooth the cast, using both hands. Make sure that it conforms to the contours of the local anatomy by using the palms to apply pressure to the cast (Fig. 187-12E). If the fingers are used to conform (or mold) the cast, subtle pressure areas under the cast may be created. After the cast is applied, plaster should never touch the patient's skin directly. Positioning of the injured area while casting is critical. The ankle joint should be at 90 degrees and the hand and wrist in a position of function (slightly extended, relaxed). This position should be closely rechecked before hardening of the cast. See Figure 187-2 for an example of the position of function used with short-arm casts. With certain fractures or tendon injuries, these positions may be altered to improve tissue healing. The provider should be aware of these needs before the application of the cast.

Application of synthetic materials follows a similar course, with a few noteworthy exceptions. Water used to activate the curing process should be kept no warmer than room temperature to avoid too rapid setting. Normally, setting occurs in 2 to 3 minutes. Because of the flexibility of the synthetic bandage rolls, tucking of edges is not necessary to avoid transverse creases. However, care must still be taken to avoid pulling the cast material too tight. Molding should occur between each layer, with most synthetic casts requiring only two to three layers of cast material, depending on the area immobilized (Fig. 187-13A to C). Strips of heavy-duty, reinforcing material are available and frequently applied (e.g., to the posterior aspect of a short-leg walking cast) to increase durability (Fig. 187-13D). After the final check of position, synthetic casts may require trimming of rough edges. If not trimmed, these edges may catch on clothing or injure the skin or soft tissue under the cast. Trimming can be done with a file, sandpaper, cast saw, or scissors, and it is done with less difficulty when the cast is still soft (Fig. 187-13E).

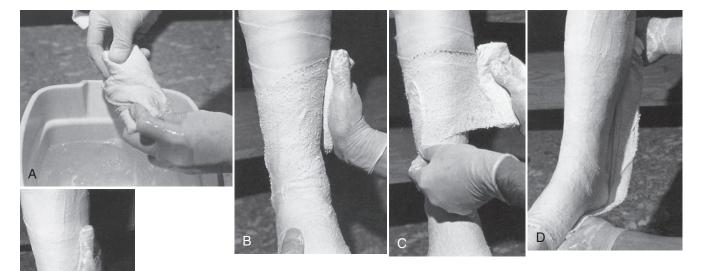

Figure 187-12 Application of plaster cast material. **A,** The plaster roll is removed from the water after the bubbles cease. The ends are pinched shut, and the roll is gently squeezed to expel excess water. Less water or excess wringing causes faster drying. **B,** Beginning at one end, the plaster is pushed onto the extremity by using gentle pressure from the thenar eminence against the middle of the roll. The roll should remain in contact with the limb and is usually not lifted from it. Additional rolls are started where the previous one ends. The roll is applied so that the opening side faces the operator and not the extremity. **C,** Tucks or pleats are taken as often as necessary to guide the roll and to accommodate any tapering of the limb. The stockinette is folded back and incorporated into the cast. **D,** Reinforcing splints five to ten layers thick applied to the sides or back add a great deal of strength without adding much weight. They are particularly useful at the ankle, where the cast is weakest and breakage is most common. **E,** The cast is molded with the flat surface of the hands, if necessary, and trimmed, especially at the small toe. (From Mercier LR: Practical Orthopedics, 5th ed. St Louis, Mosby, 2000.)

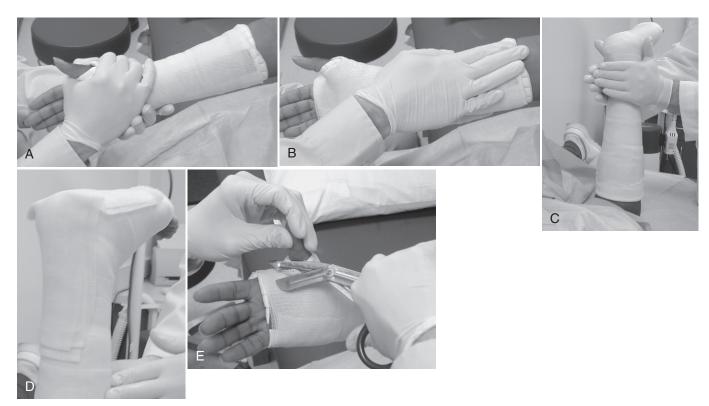

Figure 187-13 Application of synthetic materials. **A,** Molding short-arm cast at wrist. **B,** Molding short-arm cast at forearm. **C,** Molding short-leg walker at Achilles area. **D,** Position of posterior reinforcement strip for short-leg walker. **E,** Trimming excess cast material to avoid trauma to nearby skin.

#### POSTPROCEDURE PATIENT EDUCATION

After cast application, instruct the patient in proper cast care and advise of signs and symptoms that require immediate attention. For plaster, advise avoidance of unnecessary forces to the cast, such as weight bearing for at least the first 24 to 48 hours, as the material will still be in the curing process. Synthetic casts usually develop sufficient durability to bear increased forces after 12 to 24 hours. Depending on the acuity of injury, elevation for the initial 48 to 72 hours may be recommended to reduce swelling.

Crutch walking is necessary for lower-extremity injuries treated with casting until the cast has developed adequate strength to support weight bearing. Crutches that fit properly will be 1 to  $1\frac{1}{2}$  inches below the axilla when placed vertically between the arm and body. The handgrips should be adjusted to allow the patient to have slightly flexed elbows during use. It is also important to remind patients that crutches are not intended to support the weight in the axilla, since this can lead to paresthesias in the arm. The weight of the body should be supported in the hands and the unaffected lower extremity (using a three-point gait). Prior to discharging the patient, it is also helpful to observe his or her gait with the use of crutches and correct any problems that may occur.

Patients must take care to avoid getting the cast material wet and must be advised that submersion of even synthetic casts is unacceptable if routine stockinette and padding are used. If the cast should get wet, the patient may try drying it with an electric blow dryer on the cool setting, being careful not to overheat the cast material. Soaked plaster casts and synthetic casts (with traditional stockinette and padding) in which the underlying cast padding is saturated require attention by a clinician and possible replacement. If not evaluated, the patient may suffer loss of immobilization, or skin irritation or maceration from the moisture under the cast material.

The patient must never introduce foreign objects (e.g., coat hangers) underneath the cast for any reason. Strategies for the patient with

pruritus under the cast include using cool air from an electric blow dryer or talc or baby powder applied under the cast.

Patients using waterproof cast liner and fiberglass cast material may allow their cast to get wet. Bathing with mild soap is permitted. In general, a synthetic cast will require 1 to 4 hours to dry after submersion. Common sense should dictate the avoidance of swimming in areas that might allow the introduction of foreign bodies beneath the cast (e.g., fish, debris).

Cast wearers should contact their clinician if they develop increased pain in the immobilized region; numbness, tingling, or weakness in the affected area; a change in skin color distal to the cast; or persistent skin irritation.

# **CAST REMOVAL EQUIPMENT**

- An electric, oscillating cast saw
- Cast spreaders
- Bandage/trauma scissors

# PREPROCEDURE PATIENT PREPARATION

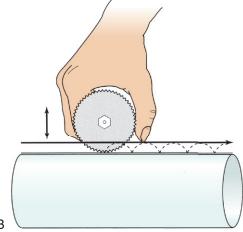

Patient counseling before starting the procedure, especially in the pediatric population, is likely to be the most effective means of minimizing fear and apprehension. Some practitioners solve this potential problem by allowing ancillary staff (nurses or other clinicians) to perform this function. In either case, it is good practice to describe the technique to the patient and include descriptions of any sensations (e.g., warmth, vibration) likely to be experienced. Actually turning the cast saw on and applying it briefly to one's own skin to show that it will not cut is sometimes used to demonstrate the safety of the procedure. The fear related to the noise generated by the cast saw can be reduced with the use of hearing protection. This may be especially helpful in the pediatric population. Once the patient is prepared, actual removal of the cast is fairly easy.

#### **TECHNIQUE**

Removal techniques differ based on previous experience and training.

- 1. Stabilize the immobilized limb, with the patient in a comfortable position and with a drape covering any clothing likely to be exposed to cast saw dust. Some patients will also appreciate wearing a surgical mask to reduce the inhalation of cast dust.
- 2. Determine the cut line before starting. If possible, avoid potentially sensitive areas. If a protective strip was utilized, the cut line is between where it appears on the cuffs at each end.
- 3. Hold the cast saw in one hand and, using the thumb and a finger (usually the index) of the other hand, stabilize the saw against the cast (Fig. 187-14). This technique allows control of the depth of cut. Constantly changing the area of the blade in contact with the cast and avoiding prolonged cutting in a single area should decrease the heat generated and limit the potential for saw-induced burns. Another technique to reduce cast saw heat production is to cut in a manner similar to a sewing machine needle. With this method the depth of the cast saw is constantly changing and exposes different areas of the saw blade to cast material. Depending on the cast material and the type of cast, either one (univalve) or two (bivalve) cuts along the entire length of the cast will be required.
- 4. After full-thickness cuts have been made through the casting material, use the cast spreaders to expose the underlying padding and stockinette (Fig. 187-15), which can then be cut with bandage/trauma scissors. If a protective strip is in place, the cast

**Figure 187-14** Cast removal. **A,** Hold the cast saw in one hand, and use the thumb and another finger (usually the index) to stabilize the saw against the cast, which prevents the blade from injuring the underlying skin. **B,** Cut down through both sides of the cast. Do not saw back and forth with the blade. Cut the cast at right angles to the material. (**B,** From Mercier LR: Practical Orthopedics, 5th ed. St Louis, Mosby, 2000.)

**Figure 187-15** Cast spreader or pliers separate the upper and lower portions of the cast, which has been cut on both sides.

- spreaders should be used frequently to locate it and thereby maintain the cut line for the saw.
- Once all material has been divided, remove the cast and allow the patient to cleanse the skin. Postprocedure cast care is injury specific and geared toward rehabilitation of the affected limb.

#### **COMPLICATIONS**

The most well-known and feared complication is the development of a compartment syndrome (see Chapter 188, Compartment Syndrome Evaluation). The process can occur with even a simple, benign-appearing injury. If a snug circumferential cast is applied and tissue swelling continues after the initial injury, conditions are set for compromise of the microcirculation to the immobilized tissue. This may lead to ischemia of the affected area, producing muscle necrosis and further edema. If this process continues untreated and compartmental pressures reach a critical level, irreversible damage to the involved tissues may ensue. Ultimately, ischemic contractures (e.g., Volkmann's) may occur with loss of limb function.

Signs and symptoms of compartment syndrome include pain that is out of proportion to the injury or is elicited with pressure over the affected compartment or with stretching of involved muscle groups. Additional indications of impending compartment syndrome include paresthesias in the corresponding dermatome, the inability to generate a forceful muscle contraction, and normal pulses in the affected limb. Pulselessness and pallor are not characteristics of compartment syndrome, because pressures will rarely rise high enough in a compartment to completely obstruct the major blood vessels in that area. All patients who receive a cast as part of their therapy should be counseled regarding the signs and symptoms of compartment syndrome. Should they occur, emphasis must be placed on the immediate need to contact the treating clinician or to seek care in an emergency department. Delayed diagnosis and treatment can lead to irreversible muscle and nerve damage.

Initial treatment in suspected cases of compartment syndrome is relief of the pressure generated by the cast, either through univalving, bivalving, or complete removal. Univalving results in a 30% drop in pressure while bivalving results in a 60% drop. Definitive diagnosis rests on characteristic signs, symptoms, and objective measurement of the compartmental pressure. Treatment of documented compartment syndrome may require surgical intervention in the form of fasciotomy.

Loss of reduction of the fracture is a possible complication. Therefore, every effort should be made to maintain the reduction as the extremity is being cast. Likewise, every effort should be made to maintain the integrity of the cast, especially as it is setting as well as afterward, when it is exposed to daily wear and the environment.

Various other skin conditions, nerve palsy, thermal injury, joint stiffness, disuse osteoporosis, and thromboembolic events may also complicate cast therapy. Of the skin conditions, cast dermatitis may be the most common, usually resulting in severe, bothersome pruritus from poor ventilation to the underlying skin. Use of absorbent powders (e.g., talc or baby powder) may help limit the incidence of this condition. Two problems may result if patients introduce objects

under the cast to relieve intense itching. First, the object may become trapped under the cast, producing a pressure point that can cause severe ulceration. Second, such instruments as coat hangers can easily lacerate the skin if used too aggressively, forming a nidus for infection or even requiring suture repair. Pressure necrosis or sores may result from poorly fitting casts that are insufficiently padded over bony prominences or inadequately molded to local anatomic contours (Fig. 187-16). As mentioned, transverse wrinkles in stockinette or cast padding or ridges in the cast material can lead to pressure necrosis. Pressure sores can occur as soon as 2 hours after the application of a cast. The patient who complains of persistent skin irritation characterized by burning or pain should be seen for evaluation and for possible opening of a window over the symptomatic area to facilitate direct examination. Additional skin damage may occur during cast removal as a result of heat generated by the cast saw. These burns are preventable with use of good technique, and their frequency may be reduced with the use of protective strips under the cast (e.g., De-Flex Strip). The use of waterproof liner under the cast material increases the chance of burns during cast removal (this should be discussed with patients prior to cast application), and the use of a protective strip under the cast material is highly recommended. Many providers have patients sign a consent form prior to using waterproof liner because of increased risk of burns and because many insurance providers do not cover the additional cost of this material.

Any cast used to immobilize an anatomic region where superficial peripheral nerves lie in close proximity to underlying bone may lead to nerve palsy. Long-leg casts and those short-leg casts involving the head of the fibula can produce a common peroneal nerve palsy as the rigid cast compresses the nerve in its course over the fibular head (Fig. 187-17). Symptoms may include loss of sensation over the dorsolateral aspect of the involved foot, and "foot drop," or weakness in the ankle dorsiflexors. Other potential areas of involvement include the ulnar nerve as it passes through the cubital tunnel region, usually seen with long-arm casts, and the median nerve as it passes through the carpal tunnel (both short- and long-arm casts). These neurologic injuries can be complete or incomplete, reversible or irreversible, and should be recognized and treated in a timely fashion.

Risk of thermal injury can be minimized by avoiding water that is too warm (>24° C/75° F) when using plaster of Paris and by avoid-

Figure 187-16 Common location for pressure sores (noted by ink on cast).

**Figure 187-17** Outline on the skin denotes the fibular head and indicates where the peroneal nerve is located. Excess pressure in this area can lead to paralysis and foot drop.

ing casting that is thicker than 10 ply. A nearly universal complaint following cast immobilization is *joint stiffness*, which is directly related to duration of immobilization. This fact should be discussed with the patient at the time of cast application and should be taken into consideration when determining length of treatment. Depending on the cause for initial treatment and response to therapy, the clinician can initiate fairly aggressive stretching exercises after cast removal to facilitate the return of normal joint function. Use of simple range-of-motion and other exercises involving nonimmobilized joints in the affected extremity (e.g., straight-leg raising, finger or toe flexion/extension) can minimize the effects of prolonged disuse. Casting in the position of function also seems to minimize the effects of disuse.

Thromboembolic complications, such as deep venous thrombosis or pulmonary embolism, can occur with cast use (usually of the lower extremity) and must be considered when patients have suspicious symptoms. Diagnosis is difficult because of the presence of the original injury and limitations in examination. To exclude the diagnosis of venous thrombosis may require cast removal and ancillary testing (e.g., duplex ultrasound).

# **CPT/BILLING CODES**

The codes for fracture treatment include application of casts and splints. The clinician cannot use these codes for the *initial* application. Use the cast application codes listed here when any of the following occurs:

- Application of cast/splint is temporary and definitive treatment will be done later or by someone else (e.g., application performed in emergency room or office for patient comfort or to temporarily stabilize an injury).
- The cast must be replaced.
- The cast or splinting is performed as an initial service for treatment and no other procedure is planned (e.g., casting of a sprained ankle). Use a casting code in addition to an E/M code.

Casting and strapping codes include removal. Use removal codes only if the cast has been applied by another clinician.

If not listed here, see CPT codes 29000 to 29799 in the CPT code book.

# **Upper Extremity Casts**

- 29065 Shoulder to hand (long arm)
- 29075 Elbow to finger (short arm)
- 29085 Hand and lower forearm (gauntlet)
- 29086 Finger (e.g., for contracture)

# **Upper Extremity Splints**

- 29105 Application of long-arm splint (shoulder to hand)
- 29125 Application of short-arm splint (forearm to hand); static
- 29130 Application of finger splint; static

# **Lower Extremity Casts**

- 29345 Application of long-leg cast (thigh to toes)
- 29355 Application of long-leg cast—walker or ambulatory type
- 29365 Application of cylinder cast (thigh to ankle)
- 29405 Application of short-leg cast (below knee to toes)
- 29425 Application of short-leg cast—walker or ambulatory type
- 29435 Application of patellar tendon bearing (PTB) cast
- 29440 Adding walker to previously applied cast
- 29445 Application of rigid total contact leg cast

# **Lower Extremity Splints**

- 29505 Application of long-leg splint (thigh to ankle or toes)
- 29515 Application of short-leg splint (calf to foot)

#### **Lower Extremity Strapping**

- 29530 Strapping, knee
- 29540 Strapping, ankle
- 29550 Strapping, toes
- 29580 Unna boot

# Removal or Repair

Codes for cast removal should be used only for casts applied by another clinician.

- 29700 Removal or bivalving, gauntlet, boot, or body cast
- 29705 Removal or bivalving, full-arm or full-leg cast
- 29730 Windowing of cast
- 29740 Wedging of cast (except clubfoot casts)
- 29799 Unlisted procedure, casting or strapping

Also see Chapter 190, Fracture Care, for appropriate ICD-9 codes.

# COMPARTMENT SYNDROME EVALUATION

Michelle E. Szczepanik • Francis G. O'Connor

Compartment syndrome occurs when the pressure inside the fascial compartment of an extremity is higher than the pressure of the blood in the vessels going into the compartment. This variance can be caused by bleeding into or edema in the area, which in turn can lead to compromise of the circulation to the soft tissues, especially the muscles and nerves, and cause tissue ischemia and eventual necrosis. If the compartment syndrome is present for 8 hours or more, irreversible tissue damage will likely occur and can lead to subsequent fibrosis and contracture of the muscles and compartment tendons. The flexor tendons are involved most often and are usually the earliest to be involved because they are in the deepest compartments of the calf and forearm. To merely monitor distal pulses for development of compartment syndrome is not adequate. An absent arterial pulse may indicate only damage to a single artery, congenital absence of an artery, or hypovolemia; conversely, normal pulses may be present despite dangerously elevated compartment pressures. Lack of pulse accompanied by pain and pallor are end-stage compartment syndrome signs and symptoms; if these are relied on to make the diagnosis, it will be too late for optimal treatment in most cases. Surgical release using an incision through the fascial compartments (fasciotomy) is required to relieve the excessive pressure.

Compartment syndrome can occur at any age but is much more common in adults than in children. Be aware that the swelling may not peak for 24 to 72 hours after an injury; therefore, the clinician needs to consider this diagnosis, perform a careful examination, and consider measuring compartment pressures up to 3 days after severe injuries.

Compartment pressures can be measured once (as a spot check), periodically, or continuously with a needle being left in place. This chapter discusses measurement of compartment pressures using a needle; wick or slit catheters can be used in a similar manner but are not covered here. Wick and slit catheters are generally used for more prolonged, in-hospital monitoring or research.

# CONDITIONS ASSOCIATED WITH COMPARTMENT SYNDROME

- Soft tissue injury only (without a fracture in forearm, calf, hand, or foot)
- Soft tissue injury with a fracture of forearm, calf, hand, or foot
- Supracondylar fracture of the elbow (Volkmann's ischemia)
- Crush injury to thigh
- Gluteal trauma
- Prolonged tourniquet application (>2 hours)
- Anticoagulated patient or patient with coagulopathy
- Electrical injury
- Burns
- Bites (e.g., dog, shark, snake) in susceptible areas
- Exercise-induced compartment syndrome

It is important to understand that compartment syndrome can occur as a result of many different types of insults. Although it is more common in the *calf* or the *forearm*, compartment syndrome can also occur in the hand, foot, thigh, or buttocks. The rule followed is the greater the amount of soft tissue trauma, the greater the chance of compartment syndrome. For this reason, any high-velocity injury should be treated with caution because the energy dissipated through the soft tissue can cause extreme swelling. Injuries commonly associated with compartment syndrome include automobile accidents and pedestrian trauma, especially bumper injuries to the buttocks, calf, or forearm.

Compartment syndrome is a common result of trauma or a fracture. "Volkmann's ischemia" is compartment syndrome in the forearm occurring after supracondylar fractures that cause a large amount of swelling around the elbow. Calcaneal fractures can also cause compartment syndrome, although this is rare. Compartment syndrome can occur in the thigh because of a severe crush injury. Gluteal compartment syndrome, which is frequently associated with an automobile accident or fall from a height, is due to the direct trauma and associated swelling of the muscle compartment. A patient with trauma, especially one with a coagulopathy or on anticoagulation, can develop bleeding into a muscle compartment, leading to increased pressure.

A chronic form of compartment syndrome can occur with exertion, usually increasing as a training program progresses. Also known as exercise-induced compartment syndrome, chronic exertional compartment syndrome presents as a gradual development of pain with activity followed by a gradual resolution of symptoms with cessation of the activity. It is more common in runners, usually involves the calf, and must be distinguished from other causes of chronic leg pain such as medial tibial stress syndrome, stress fracture, nerve or arterial entrapment, or muscle strain. A good history and postexercise examination are fundamental in differentiating between these different causes of chronic leg pain.

Finally, some less common but certainly notable causes of compartment syndrome include prolonged use of a tourniquet, large animal bites, snakebites, infection, electrical injuries, and burns. Prolonged application of a tourniquet (>2 hours) has been associated with development of compartment syndrome when the tourniquet is released and reperfusion causes swelling and increased pressure. Bites in an extremity from large animals such as sharks or dogs can cause crush injuries; snakebites are also associated with significant edema. Scratches, cuts, or bites from smaller animals or insects can result in infection that may cause a compartment syndrome or mask or restrict one. Patients who have electrical injuries, with or without a visible skin burn, can develop compartment syndrome. The mechanism is similar to that of a device available on the market to cook a hot dog, which is how the injury got its nickname "hot dogger." After a hot dog is punctured at both ends with

a metal spike, an electrical current is delivered through the hot dog. This causes intense heat, thus cooking the hot dog. The same mechanism occurs with burn injuries with an entrance and exit point for the electrical energy. The "cooked" tissue inside swells, nearly to the point of bursting, but is restrained by the surrounding tissue. The extent of injury may not be visible on the patient's initial visit but can develop over the next 1 to 3 days. A clinician should always consider compartment syndrome when evaluating burns of any source.

# CONDITIONS THAT CAN CREATE, MASK, OR WORSEN COMPARTMENT SYNDROME

- Applying heat to injury
- Spinal cord injury or regional anesthetic block
- Intoxication, altered mental status, or changes in sensorium (e.g., head trauma, coma)
- Infection, burns, scarring, tight bandages, or being in a cast

An injury, with or without fracture, that is later subjected to warm water or any other intervention resulting in vasodilation will have increased swelling and an increased chance of compartment syndrome. Patients with a severe bruise from a fall who then soak it in a hot tub of water can develop compartment syndrome. It can also happen when expansion of the soft tissue envelope (skin) is constricted by a cast, scarring, or infection. If any patient has pain out of proportion to objective findings, especially after trauma to an extremity or placement of a cast, the cast and Webril should be removed entirely and the patient examined carefully for compartment syndrome. If removal of the cast and Webril does not bring immediate and complete relief of the intense pain, evaluation for compartment syndrome is indicated (with subsequent surgical treatment if present). Even without a cast, any feeling of tense, tight swelling in the forearm, hand, calf, or foot should lead to suspicion of compartment syndrome.

Another presentation for compartment syndrome is the intoxicated individual who falls and sustains an injury. Because of the intoxication (or any other reason for an altered sensorium), the pain is ignored. In addition, patients who have a spinal cord injury resulting from a motor vehicle accident will not have pain in the forearm or calf in spite of the swelling that may also occur as a result of the accident. Postoperative patients with a regional block may not have pain for the same reason. For the aforementioned reasons, immediate evaluation may be necessary and a fasciotomy considered in any such patient with a tense and swollen forearm, calf, hand, or foot.

# **INDICATIONS**

A diagnosis of compartment syndrome made after loss of pulses and loss of capillary refill comes too late for optimal treatment. The most important and earliest symptom associated with compartment syndrome is *pain*. If pain after an injury is associated with swelling in an extremity and the pain is not relieved by medication (e.g., up to one or two Percocet tablets every 4 hours), compartment syndrome should be suspected, especially if the pain is progressive.

The earliest physical findings are (1) loss of fine touch and (2) pain with extension of the great toe or the thumb. Compartment syndrome most commonly occurs first in the volar/dorsal compartment of the forearm, where the long flexor tendon of the thumb travels, and in the calf, where the long flexor tendon for the great toe is located. By passively extending the thumb or great toe, the muscle tendon unit in this deep compartment is stretched. If the muscle is ischemic because of early compartment syndrome, pain will be present and increased by extension of the thumb or toe. Two-point discrimination is also impaired early.

For chronic exertional compartment syndrome, certain symptoms help distinguish it from other causes of chronic leg pain. Aching or cramping leg pain, gradual rather than immediate devel-

opment of pain with activity, neurologic symptoms such as numbness or tingling, gradual resolution with cessation of activity, and shorter distances or intensities being required to produce the discomfort are all typical symptoms. Because routine physical examination is usually negative, a postexercise examination should be included to demonstrate tightness of the compartment involved, discomfort and tenderness with palpation, and involvement of the muscle mass rather than the muscle—tendon junction. The calf is most commonly involved, and about 80% of the time compartment syndrome occurs bilaterally.

Measurement of compartment pressures should be considered in any patient with a compatible history, a swollen and tense muscle group, and

- Pain (the earliest and most sensitive symptom)
- Pain out of proportion to objective findings, especially if progressive
- Increasing pain not relieved by usual narcotic pain medication
- Loss of fine touch or two-point discrimination
- Pain with passive motion of the affected muscles (e.g., extension of great toe or thumb of affected limb)
- Increased discomfort when muscle trapped in fascial compartment is moved (actively or passively), especially the flexor muscles
- Excessive constriction of the affected compartment
- Suspected chronic exertional compartment syndrome

#### **CONTRAINDICATIONS TO MEASUREMENT**

- When compartment syndrome is clinically obvious and measurement would delay definitive treatment
- Cellulitis directly over the area to be measured (relative contraindication)
- Anticoagulation (relative contraindication)

# PREPROCEDURE PATIENT PREPARATION

Indications, alternatives, risks, potential benefits, and expected results should be discussed with the patient or representative and signed informed consent should be obtained. The patient should expect some discomfort as needles are inserted. The procedure may need to be repeated at various locations and intermittently over time. Alternatively, a continuous monitor may be left in place (usually in a comatose patient). Let conscious patients know they will be warned before insertion of a needle. It will also be important for them to remain very still during certain portions of the procedure. If moderate (conscious) sedation is to be used, intravenous access should be obtained and the patient should be monitored with pulse oximetry.

#### **EQUIPMENT**

- Gloves and other necessary equipment for the clinician to follow universal blood and body fluid precautions
- Povidone-iodine (Betadine) or chlorhexidine (Hibiclens) antiseptic solution
- Sterile drapes and towels
- 4 × 4 gauze squares
- Band-Aids to cover needle insertion sites
- Local anesthetic (1% lidocaine), syringe, and needles (optional)

#### Stryker System

- Prefilled syringe with saline
- Side-port needle
- Diaphragm chamber
- Hand-held pressure monitor
- Stryker 295 quick-pressure monitor set (disposable pouch)

**Figure 188-1** Stryker 295 intracompartmental pressure monitor system. (Courtesy of Stryker Instruments, Kalamazoo, Mich.)

# Needle-Manometer or Arterial-Type Transducer System

- Two 18-gauge needles (18-gauge spinal needle may be needed for deep measurements such as thigh or gluteal compartments)
- Two sets of extension tubing
- 20-mL syringe
- Three-way stopcock
- Sterile normal saline solution
- Manometer or pressure transducer, cable, monitor, and adjustable transducer stand

Clinicians primarily use one of two pressure measurement systems, either the Stryker 295 intracompartmental pressure monitor system, which is a portable penlike compartment pressure device made by the Stryker Company, or a needle–manometer or arterial-type transducer system. The Stryker 295 (Fig. 188-1) is much like a tonometer for measuring glaucoma. All of these systems can also be converted to a continuous monitoring system.

# **TECHNIQUE**

Each body "compartment" can become compromised. Various compartments are shown in Figs. 188-2 to 188-13. Suggested sites for placement of the needle are noted in Table 188-1. Most experts recommend multiple measurements at multiple sites with at least one being at the site of maximal tightness as determined by the examining clinician. A study by Whitesides and Heckman (1996) suggests that with fractures, measurements should be performed at the level of the fracture as well as locations proximal and distal to the zone of the fracture. They used a distance of 5 cm proximal and distal to the fracture site.

#### **General**

- 1. Obtain informed consent.
- The compartment to be measured should be at the level of the patient's heart and positioned so the needle can enter perpendicular to the compartment.
- Avoid any external pressures to the area; the region tested may need to be slightly elevated off the bed by an assistant. The patient must be cooperative and not move or contract the muscle group.
- 4. Prepare skin with antiseptic solution. Sterile technique should be maintained when setting up the equipment and inserting the needles. Sterile drapes should be used if more than one measurement is to be obtained.
- 5. A superficial local anesthetic can be given.
- When taking pressure measurements, squeeze the involved area to see if pressure increases (or have the patient contract the affected muscle), which confirms that the unit is functioning.
- 7. Consider measuring opposite-side pressures as a control and if there is any question about proper readings on affected side.
- 8. When the needle is pulled between measurements, flush it to be sure it has not become plugged with blood or tissue. After measurements are obtained, needle insertion sites should be covered properly (e.g., with a Band-Aid).

# Stryker System

- 9. Open the disposable Stryker 295 quick-pressure monitor setup.
- 10. Assemble the equipment (Fig. 188-14).
- 11. Open the cover of the monitor and insert the chamber into the device well with the block surface down. Be sure it is firmly in place.
- 12. Snap the cover closed.
- 13. Remove the syringe cap and insert the plunger.
- 14. Purge the system of air. Tilt the end of the needle up 45 degrees and slowly fill the system with saline. The saline must not roll back into the transducer well.
- 15. Turn on the unit. Readings should be between 0 and 9 mm Hg.
- 16. Simulate the angle of insertion and press the "zero" button. If the monitor does not read "00," there is a problem. Review the instructions supplied with the kit if necessary. A reading of "00" must be displayed or readings will be inaccurate.
- 17. Insert needle into the tissue.
- 18. Inject up to 0.3 mL of saline.
- 19. Read the pressure once it stabilizes.
- 20. Repeat readings by turning the unit off and withdrawing the needle and repeating the previous steps.

**Figure 188-14** Stryker 295 intracompartmental pressure monitor system assembly. (Courtesy Stryker Instruments, Kalamazoo, Mich.)

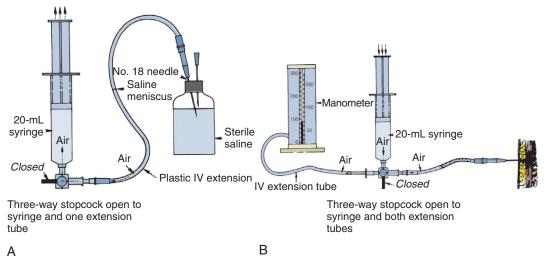

Figure 188-15 Needle—manometer technique for compartment pressure monitoring. **A,** Drawing up saline to partially fill tubing. **B,** Completed system setup with needle inserted into compartment. (From Whitesides TE Jr, Haney TC, Morimoto K, Harada K: Tissue pressure measurement as a determinant for the need of fasciotomy. Clin Orthop 113:43–51, 1975.)

# **Needle-Manometer System**

Equipment for the needle–manometer technique is readily available and the least expensive but also the least accurate.

- 9. Prepare setup (Fig. 188-15A). Use one 18-gauge needle to ventilate the sterile saline solution (i.e., ventilate by inserting the needle, which opens the bag or bottle to atmospheric pressure and breaks the vacuum in the bottle or bag). This needle should be left in place, ventilating the saline, during the next step, while the extension tubing is being partially filled with saline.
- 10. Attach the 20-mL syringe to the stopcock. Attach one extension tubing (with the other 18-gauge needle attached) to another port on the stopcock.
- 11. Using the 20-mL syringe, draw enough saline into the extension tubing to fill it about halfway. Then close the stopcock to the extension tubing. Be sure there are no air bubbles in the saline in the extension tubing.
- 12. Remove the syringe from the stopcock and fill it about with about 15 mL of air. Reattach it to the stopcock.
- 13. Attach the other extension tubing to the stopcock. Attach the opposite end of this tubing to a manometer (Fig. 188-15B).
- 14. With the stopcock still closed to the extension tubing with the needle attached, pull the needle out of the saline. Insert the needle into the desired compartment for pressure measurement (see Table 188-1). For deep measurements (thigh or gluteal compartments), an 18-gauge spinal needle may be needed.
- 15. Slowly depress the syringe plunger. This gives the manometer time to move. Watch the meniscus on the column of saline in the extension tubing. When it flattens, right before the saline starts moving in the tubing, the pressure in the syringe has matched tissue pressure. Note the reading on the manometer, which is the compartment pressure.
- 16. Check a second recording by removing the needle and repeating as previously.

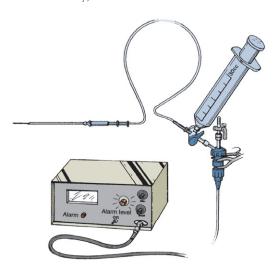

# **Arterial-Type Transducer System**

Also see Chapter 208, Arterial Puncture and Percutaneous Arterial Line Placement.

Equipment for the arterial-type transducer system is also usually readily available. In the emergency department, the operating room, or the critical care unit, the nurse or respiratory therapist can often assist with flushing and hooking up the extension tubing, which is

attached to a pressure transducer. The nurse or respiratory therapist also usually know how to assemble and calibrate the rest of the equipment.

- 9. Connect the cable to the monitor.
- 10. Assemble the equipment (Fig. 188-16). Using one 18-gauge needle, fill the 20-mL syringe with sterile saline. One extension tubing will be used to connect the stopcock to the transducer; the other will have the other 18-gauge needle attached.
- 11. Attach the 20-mL syringe to the stopcock and fill the transducer, both sets of extension tubing, and the attached 18-gauge needle with saline. Close the stopcock to the extension tubing attached to the 18-gauge needle.
- Remove the 20-mL syringe and open the stopcock to air. Place the transducer at the level of the muscle compartment where pressures are being measured.
- 13. Calibrate to zero and close the stopcock.
- 14. Open the stopcock to the extension tubing with the 18-gauge needle attached (which will now be called the "arterial line" because the pressures will be measured and monitored like that of an artery) and insert the needle into the muscle

**Figure 188-16** Arterial-type transducer system for compartment pressure measurement. (From Rorabeck CH: Compartment syndromes. In Browner BD, Jupiter JB, Levine AM, Trafton PG [eds]: Skeletal Trauma: Fractures, Dislocations, Ligamentous Injuries, vol 1, 2nd ed. Philadelphia, WB Saunders, 1992.)

compartment. Squeeze (or have the patient move) the muscles of the desired compartment. Pressures should elevate on the monitor. Allow the muscles to rest and measure the pressure.

 Pull the needle and repeat the process for a second confirmatory measurement.

NOTE: Attempts should be made to minimize the injection of saline into the compartment being measured because it may elevate the pressure for subsequent measurements or worsen the compartment syndrome. Using a partially air-filled 20-mL syringe and a partially filled "arterial line" extension tubing, the technique described with the needle—manometer setup can also be used with the arterial-type transducer system. As the air-filled syringe is depressed, when the meniscus flattens and the saline starts moving toward the compartment, the measurement on the monitor will be equal to compartment pressure.

#### **CRITERIA TO PERFORM FASCIOTOMY**

- Compartment pressure reading over 30 mm Hg
- High clinical suspicion despite normal pressure readings (symptoms of pain out of proportion to objective findings, decreased sensation and pain with passive extension of the thumb or great toe, a tense compartment with clinical signs of compartment syndrome)

Healthy compartment pressures range between 0 and 8 mm Hg. Readings in all compartments should be 30 mm Hg or below. Any reading above that level requires immediate consultation for possible surgical treatment of compartment syndrome. Compartment pressures 10 to 30 mm Hg below the patient's mean arterial pressure or the patient's diastolic pressure may also indicate need for a fasciotomy. If multiple measurements are taken, some experts recommend using the highest measured pressures to make the decision for further intervention.

Do not rely solely on pressures to make clinical decisions. Fasciotomy may be indicated if the compartment is tense to palpation, if there is pain out of proportion to objective findings, or if there is decreased sensation and pain with passive extension of the thumb or great toe. If any of these findings are present, even in the face of what appears to be normal compartment pressures, consultation should be obtained immediately. Compartment pressure measurements can give false-normal readings at times. Therefore, such measurements are of value only when combined with the other information on physical examination and pain level.

# CRITERIA FOR DIAGNOSIS OF CHRONIC EXERTIONAL COMPARTMENT SYNDROME

Once history and physical findings support the diagnosis, compartment pressures should be measured at rest followed by postexercise pressures after pain is reproduced. One of the following criteria must be met for the test to be positive:

- A pre-exercise compartment pressure greater than 15 mm Hg
- One-minute postexercise compartment pressure greater than 30 mm Hg
- Five-minute postexercise compartment pressure greater than 20 mm Hg

## **COMPLICATIONS**

- Bleeding
- Infection
- Increased pressure from extra fluid injected
- Pain
- Inaccurate, falsely reassuring readings

Each of the first three (bleeding, infection, increased volume of fluid) could exacerbate a compartment syndrome.

# EXTENSOR TENDON REPAIR

David T. Bortel

Acute extensor tendon injuries are common and for the most part may be addressed surgically as an outpatient procedure in an acute care setting with proper equipment. Extensor tendons are located superficially and are therefore very vulnerable to trauma. The specialized elastic fatty tissue that allows tendons to glide over the hand, forearm, or dorsum of the foot is called paratenon. This vascularized, filmy connective tissue envelops the extensor tendon and does not readily separate when lacerated. This makes these injuries more amenable to repair with less need for significant dissection compared with flexor tendons. However, the practitioner should not ignore the complexity of the extensor mechanism. In the hand, most clinicians consider the act of finger extension to be more intricate than finger flexion. The act of extension comprises two separate and neurologically independent (yet interdependent) systems: the extrinsic extensor system, originating from the forearm and innervated by the radial nerve, and the intrinsic extensor system, originating in the hand and innervated by the median and ulnar nerves (Fig. 189-1).

For years, extensor injuries have been classified by zones of injury (Kleinert zones; Fig. 189-2). Each zone has uniquely associated injury patterns and therefore different modes of treatment. Greater than 50% of extensor tendon injuries are accompanied by another injury (e.g., fracture, dislocation/ligamentous injury, capsular damage, or flexor tendon injury).

#### **PRINCIPLES**

Penetrating trauma to the dorsum of the hand needs to be examined carefully for any loss of the neurovascular status or motor/tendon function. The wound should be anesthetized and explored to visualize the potentially involved tendon; the wound should be extended, if necessary, to understand the personality of the specific injury (Fig. 189-3). When a tendon is completely transected, the cut ends can retract a considerable distance. Because a partial tendon laceration might appear to have full function on examination, the wound must be evaluated judiciously. Unrepaired partial tendon lacerations can result in delayed rupture 1 to several days after the initial injury. The entire tendon complex must be observed throughout the entire arc of motion at the injury location and function compared with that of the unaffected same finger on the opposite hand. Most practitioners believe a repair is warranted if 50% or more cross-sectional damage has occurred. After closure, a tendon repair must have healthy padded skin above it for viability, or tissue grafting will be necessary. Wounds older than 6 to 8 hours need aggressive cleansing with strong consideration toward leaving the wound open for a later staged irrigation or débridement with subsequent closure. During this interval, exposed bone, joint, and tendon tissue should be loosely covered with native tissue or a damp sterile gauze followed by a bulky dressing and an anterior-posterior splint,

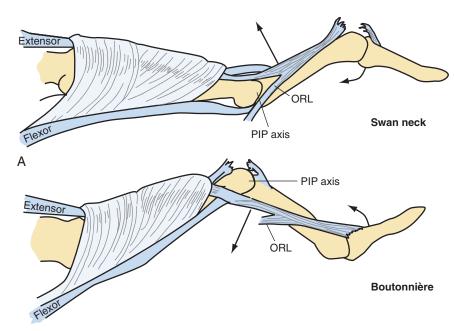

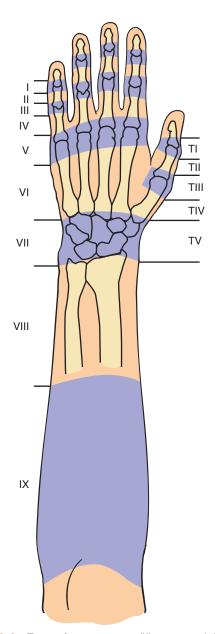

Figure 189-1 Note the intimate working relationship of the intrinsic and extrinsic extensor mechanisms. (Note that the flexor is not shown.) **A,** Mallet finger (zone I injury) that has resulted in a swan-neck deformity because the oblique retinacular ligament (ORL), also known as the conjoined lateral bands, has subluxated dorsal to the axis of rotation at the level of the proximal interphalangeal (PIP) joint. **B,** A zone III injury allows the ORL to subluxate volar to the axis of rotation at the PIP joint, resulting in a boutonnière deformity.

**Figure 189-2** Zones of extensor injury (Kleinert zones). The extensor mechanism can be injured from the fingertip to the proximal forearm. Corresponding zones in the thumb are referred to as "T" plus the zone number.

**Figure 189-3** Exploration of an extensor tendon injury over the meta-carpophalangeal joint with wound extension for appropriate visualization. (Courtesy of John Lubahn, MD.)

extending from fingertip to forearm. Tendon repair may be delayed up to 7 days.

A repaired tendon develops a fibroblastic bulbous connection during the first 2 weeks. Tendon collagen usually does not begin to form until the third week. At the end of the fourth week, swelling and vascularity will decrease. Once the junction becomes strong, the tendon can tolerate active gliding; therefore, physical therapy and rehabilitation can be initiated. Knowledge of appropriate splinting and necessary therapy is essential when caring for these injuries. Repaired tendons usually are immobilized to promote healing and to prevent tendon rupture. After hand extensor tendon repair, the splint typically can be placed on the dorsal surface from the forearm to the fingertips to protect and prevent active extension. The digits and wrist may be slightly flexed within the tolerances of the splint. These joints must be protected against flexion when changing dressings or splints. After a 3-week period of immobilization, depending on the particular circumstances, passive motion can generally be initiated under the guidance of a skilled hand therapist. Reasonable strength may return to this repaired tendon as early as 6 weeks after the injury, again depending on the patient's reliability and health status (e.g., neurologic status, tobacco use, metabolic and rheumatologic issues). Protected, nonloaded motion with a dynamic splint under the supervision of a hand therapist is increasingly chosen for postoperative care.

The vast majority of *flexor tendon* injuries should be treated by a clinician trained to repair these injuries in an appropriate surgical suite. In particular, flexor tendon injuries located in "no-man's land" (between the proximal palmar crease and the proximal interphalangeal joint) are significantly challenging. Results of tendon repair are consistently better when fixed primarily (within 7 days) rather than secondarily (after 7 days or delayed). Familiarity with the sources referenced is encouraged if managing tendon injuries (Baratz and colleagues, 2005; Hutson and Rovinsky, 2004; Thompson and Peimer, 2001; Wright, 2003).

#### **CONTRAINDICATIONS**

- Less than 50% of the extensor tendon is lacerated and the finger functions as well as the same finger on the unaffected opposite hand.
- Clinician is unfamiliar with the anatomy of the hand or lacks the skills necessary for these repairs (in this situation, the wound should be loosely closed, the hand splinted, and the patient referred).
- There is an open joint space, a bony fracture, or inadequate soft tissue or skin to cover the defect or the subsequent repair (generally in this situation, the wound should be loosely closed, the hand splinted, and the patient referred).
- By zone (see Fig. 189-2)
- Zone I open laceration: extensor tendon remnants are too short to repair.
- Zone II (except in the thumb): extensor tendon remnants are too thin to repair.
- Zones III and V: consider referral if tendon laceration has actual or potential joint or lateral band involvement.
- Zone VII: consider referral if there is actual or potential extensor retinaculum involvement.
- Zone VIII: consider referral if there is actual or potential need for tendon transfer. The wound should be loosely closed, the hand splinted, and the patient referred.

# **EQUIPMENT**

- Surgical prep solution (e.g., povidone-iodine, chlorhexidine; from hand to elbow with particularly thorough cleansing of the contaminated tissues)
- Ruler marked in centimeters
- Irrigation device for contaminated wounds: 30-mL syringe with 18-gauge angiocatheter or commercially manufactured splash

shield device (see Chapter 22, Laceration and Incision Repair, Fig. 22-1) and sterile saline

- Appropriate anesthetic (see Chapter 4, Local Anesthesia, and Chapter 8, Peripheral Nerve Blocks and Field Blocks)
- 3- to 20-mL syringe
- 27-gauge, 1½-inch needle (small-gauge needles are preferred to administer anesthesia)
- Additional 27-gauge, 1½-inch needles (useful to pierce and stabilize tendon end; optional)
- Sterile drapes; fenestrated drape applied over the lesion; appropriate larger barrier as indicated
- 4×4 gauze sponges; sterile cotton-tipped applicators are also useful
- Sterile pack containing 4½-inch needle holder; curved dissecting scissors; one or more mosquito hemostats; suture scissors; Adson forceps with and without teeth; skin hooks; small self-retaining retractor (e.g., Alm, Holzheimer, Weitlaner)
- Additional small (micro) instruments (may be helpful depending on the size of structures)
- No. 15 blade for excisions or wound lengthening with blade handle (or single disposable scalpel)
- Pack of folded sterile towels for patient arm positioning and clinician wrist support
- Appropriate suture: usually a 4-0 braided, nonabsorbable suture such as Tycron, Mersilene, or Ethibond for the tendon; a fine monofilament (e.g., 5-0 to 7-0 nylon) suture for closing the epitenon (see following text for specifics); also a monofilament (e.g., 4-0 to 5-0 nylon) suture for closing the skin (see Chapter 24, Laceration and Incision Repair: Suture Selection)
- Allis forceps for removal of deeper masses (optional)
- Skin-marking pen
- Electrocautery unit
- Specimen jar (if necessary)
- Sterile gloves
- Mask
- Protective glasses with shield
- Sterile gown
- Arm board
- Mayo or instrument holding stand draped in a sterile manner
- ½-inch Penrose drain (to tag and protect critical structures)
- Appropriate finger or arm tourniquet (with routine use precautions; the maximum time for tourniquet application is generally 2 hours)
- Comfortable chair
- Operative microscope or magnifying loupes, particularly if considering neurovascular repair (optional)

#### **Suture Material Considerations**

Suture preferences can be quite variable among clinicians who perform tendon repairs. Currently, experienced clinicians usually choose nonabsorbable suture. (Absorbable materials such as Vicryl can precipitate an inflammatory response, which might lead to excessive tendon adhesion formation. Furthermore, an absorbable suture tends to break down while the tendon is very weakened and prone to failure.) If the tendon is of sufficient size with a transected pattern, most clinicians will place one or two "core sutures" using a braided, nonabsorbable material such as Tycron, Mersilene, or Ethibond (usually 4-0 is a good size for the repair, depending on the tendon size). If a running or interrupted epitenon repair is performed, ideally a fine monofilament material is implemented. This commonly will range from a 5-0 to a 7-0, with nylon being a frequently used material. Other suture material can be considered, depending on the clinician's preference and experience. Appropriate suture for the wound closure will also be needed (see Chapter 24, Laceration and Incision Repair: Suture Selection).

## PREPROCEDURE PATIENT PREPARATION

The risks, benefits, alternatives, and actual procedure should be explained to the patient. Informed consent should be obtained. If

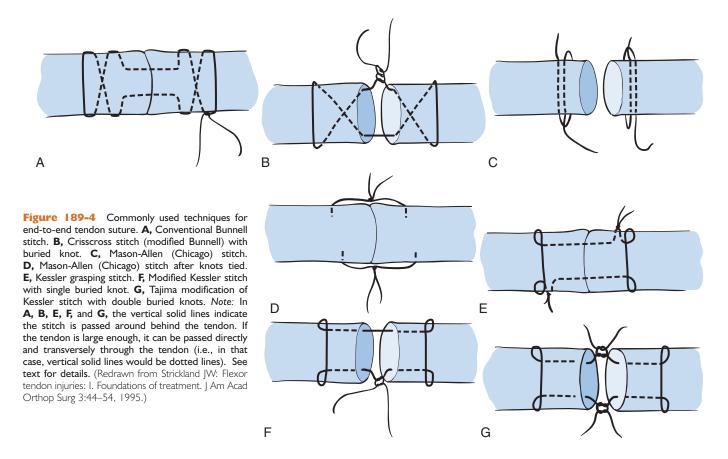

irrigation is necessary, this should be explained to the patient as well as the fact that he or she may feel some discomfort when the local anesthetic is being injected. Patients should understand the importance of remaining still during the procedure. They should be placed in a comfortable position, generally supine, in which they can remain still throughout the procedure.

## **TECHNIQUE**

Radiographic evaluation of the injured area is useful to rule out any residual foreign material in the soft tissues. Sometimes, depending on the mechanism, an unsuspected fracture might also be present. This information might influence the treatment plan. After verifying appropriate anesthesia (usually a digital or wrist block; see Chapter 8, Peripheral Nerve Blocks and Field Blocks) and completion of a thorough preparation and draping, the wound should be explored carefully to further delineate the injury. The clinician should follow universal blood and body fluid precautions. An additional irrigation and débridement might be necessary, depending on the nature of the injured tissues and if further foreign material is discovered. Any nonviable tissue must be removed. One should have little reluctance to extend the wound proximally and distally to understand the extent of the trauma, to satisfactorily visualize the damaged tissues, and to gain access to proximal and distal segments of the involved tendon(s). Electrocautery and a tourniquet are most useful to ensure appropriate hemostasis (although the maximal time for tourniquet application is generally 2 hours, most clinicians should not be performing a procedure that takes this long in the outpatient setting). Because these repairs can be quite tedious, most clinicians will perform them seated in a comfortable chair with the patient's arm positioned out to the side on an arm board. The primary surgeon will usually have his back facing the patient's head, allowing greater access to the extensor portion of the forearm and hand. With a large sterile field including the elbow through the hand and a sterile-gowned clinician, contamination is less likely when positioning the patient and providing stable wrist supports for the clinician performing these procedures.

Ragged tendon ends should be trimmed to allow a clean and direct reapproximation. It is imperative that the clinician be familiar with the associated anatomy for consideration of possible neurovascular injury. If a neurovascular injury is discovered, further referral to an experienced upper extremity surgeon is warranted. If critical structures are near the repair area, the clinician should take special precaution to protect these structures. Incomplete tendon lacerations can be repaired directly or débrided if considered an insignificant portion of the tendon. Occasionally, a tendon is lacerated in an oblique fashion, which is usually amenable to a direct repair with a fine nonabsorbable material. Most clinicians recommend a direct end-to-end (rather than side-to-side) repair of transverse extensor tendon lacerations. If a tendon has adequate substance, a "core" suture, particularly with a braided, nonabsorbable material is implemented. Typically one or two core sutures are placed. The stitch ideally has a buried knot (Fig. 189-4). A Kessler or Bunnell stitch or their modifications are commonly used, and these sutures redirect the force of the tendon perpendicular to the longitudinal axis to allow it to heal. Although no study has determined the optimal stitch for repair in each zone of injury, the modified Kessler and modified Bunnell stitches have been shown to produce the greatest strength for a core-type tendon repair. Although the literature supports the use of these modified core-type stitches, certain experts find them less useful in zones IV and VI because the tendons are so thin. These core-type stitches are most useful when repairing rounder, thicker tendons.

**NOTE:** If the tendon is not very thick, a loop of suture can be passed around the tendon (the solid vertical lines in Figs. 194-A, B, E, F and G). Granted this loop outside the tendon may later interfere with the tendon's ability to glide in its sheath, it may also be what is needed to best reapproximate the lacerated ends. If the tendon is

thick enough, the core suture can be passed directly and transversely through the tendon (in that case, the solid vertical lines in Figs. 194-A, B, E, F and G would be drawn as dotted vertical lines) which is how many experts have been suturing tendons for years.

Many clinicians use an epitenon running suture with or without a core stitch. The epitenon repair usually is with a fine, monofilament, nonabsorbable material that is appropriate for the size of the structures being repaired (Fig. 189-5). Simple interrupted sutures commonly fail by pulling through the tendon ends and fraying the tendon because of the fiber alignment. When the sutured tendon ends are brought together, a secured knot is present with minimal trauma to the tendon ends. During the repair, the tendon ends should be handled in an atraumatic technique with minimal tissue crushing. (Ideally, the tendon ends should be handled only by the clinician's fingers. Nontoothed forceps can also be quite helpful. A 27-gauge needle can be used to pierce the tendon perpendicularly and stabilize it, as can a single suture placed temporarily through the tendon. Traumatizing the tissue can result in disruption to the vascular and nutritional supplies and subsequent adhesions.) The approximated tendon ends should not buckle or be

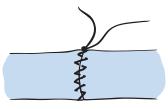

Figure 189-5 Simple running suture used for peripheral epitenon tendon repair. A locked running suture can also be used for greater strength.

compressed excessively. A flat end repair promotes proper healing and return of the proper gliding action to the tendon. Particular considerations regarding the anatomic zones are detailed in the following sections.

#### BY THE ZONES

#### Zone I: Distal Interphalangeal Joint

An extensor tendon disruption in this zone is by definition a "mallet finger" (flexion deformity at the distal interphalangeal [DIP] joint; see Fig. 189-1) unless the laceration is incomplete. These sometimes will progress to a "swan-neck" deformity as the conjoined lateral bands subluxate dorsally, resulting in proximal interphalangeal (PIP) joint hyperextension with the associated mallet deformity (see Fig. 189-1). Zone I injuries are commonly missed, especially when not associated with an open/laceration injury. These injuries usually occur when an athlete or manual laborer "jams" the fingertip. These frequently have a poor outcome, often needing a DIP fusion because the incomplete extensor mechanism at the unstable DIP joint interferes with dexterity and leads to subsequent arthritic changes at this joint.

Zone I injuries are classified into four subtypes:

- Type I: Closed or blunt trauma with loss of tendon continuity with or without a small avulsion fracture
- Type II: Laceration proximal to the DIP joint with loss of tendon continuity
- Type III: Deep abrasion with loss of skin, subcutaneous cover, and tendon substance
- Type IV: (1) Transepiphyseal plate fracture in children, (2) hyperflexion injury with fracture of 20% to 50% of the articular surface, (3) hyperextension injury with fracture of the articular

surface usually greater than 50% and with fairly early volar subluxation of the distal phalanx

A radiograph should be obtained with the lateral projection of the DIP joint being scrutinized. Fractures (typically interarticular) should be stabilized appropriately. Commonly, the fracture will need to be pinned.

#### **Treatment**

If not open, all zone I injuries should be splinted in extension or even hyperextension across the DIP joint (a digital block may be needed). Open lacerations can be repaired with care to avoid the vulnerable germinal nail matrix. These patients should be directed to a clinician who is skilled in treating these injuries. A temporary, retrograde, buried pin in full extension is often better tolerated than external splinting.

# Zone II: Middle Phalanx and Thumb Proximal Phalanx

Zone II injuries typically can be treated similarly to zone I injuries. Many of these injuries are associated with a crush. The splint must be extended to include the PIP joint.

# Zone III: Proximal Interphalangeal Joint

An injury at this location frequently will lead to a "boutonnière" deformity (see Fig. 189-1). A zone III deformity (and the previously noted mallet finger) are the most commonly missed closed injuries of the hand. The central slip is injured and the lateral bands can migrate in a volar direction past the axis of rotation at the PIP, resulting in a PIP flexion contracture with or without hyperextension at the DIP joint. Many patients have an associated collateral ligament or volar plate injury. If not recognized and treated early, no good salvage operation can restore normal function to these injuries.

#### **Treatment**

The PIP should be splinted in extension, possibly incorporating the DIP joint in extension. The patient should be referred to a clinician trained in these complex problems to have definitive care initiated within 7 days.

# **Zone IV: Proximal Phalanx**

These injuries are normally easy to identify. The lateral band extension is rarely completely transected. A nonabsorbable suture repair, followed by protected motion while the PIP joint is splinted in extension, is typically used. Consider a bite wound (see next section, Zone V).

# Zone V: Metacarpophalangeal Joint

Zone V injuries are *frequently* from a human tooth. Obtain a radiograph to rule out a fracture or foreign body. If there is *any* chance of a bite wound, it should be cleansed aggressively and *left open* with consideration of appropriate antibiotic coverage. Frequently, the metacarpophalangeal joint capsule is penetrated. Thus, these wounds should be opened, carefully explored in flexion and extension, and then normally left open (see Fig. 189-3). The hand should be splinted for later wound inspection and delayed tendon repair. An experienced practitioner can repair the wound primarily if it is considered *noncontaminated* and *not* associated with a bite wound.

**NOTE:** At this level of injury, disruption of the sagittal bands of the extensor hood may occur (e.g., dislocation of the extensor tendon) acutely or spontaneously. These injuries should be splinted and directed to a clinician skilled in managing hand and tendon injuries.

# Zone VI: Metacarpal Level

A primary repair can be pursued routinely. Buried core sutures are the typical technique used. The practitioner must oversee a careful splinting and therapy program. Again, consider a bite wound.

#### Zone VII: Wrist Extensor Retinacular Area

Zone VII injuries may be repaired similarly to zone VI injuries, realizing that the extensor retinaculum is involved and may need repair or resection. Post-traumatic adhesions are not uncommon; hence many clinicians refer all zone VII injuries for retinaculum repair. These injuries should be managed with added diligence during hand therapy.

# **Zone VIII: Distal Forearm**

Zone VIII injuries may be treated similarly to zone VI and VII injuries. At this level, adjacent structures can easily be injured, retracted, and difficult to appreciate. Sensory cutaneous nerves (radial branches and the antebrachial cutaneous nerve) should be protected carefully if in the field and repaired if observed to be lacerated.

#### **Zone IX: Proximal Forearm**

Zone IX injuries are frequently associated with neurovascular trauma. These injuries should be explored in an operating room by a clinician skilled in treating these problems.

If the practitioner has experience with extensor tendon injuries and is comfortable with splinting and therapy programs, repairs of zones IV through VI and maybe VIII can be addressed in an emergency department or an appropriately equipped office, if the inherent problems of each zone are understood. The remaining zones might be repaired in these settings relative to the clinician's experience and available equipment. The potential complications associated with these injuries and their repairs must be followed carefully. Complications can be quite significant, including primary failure of the repair, secondary later rupture of the tendon, stiffness, contractures with limited range of motion from resultant adhesions, residual pain, residual overlying tissue problems, infection, and problems related to other adjacent structures. The practitioner will never be faulted for leaving a wound open and splinted after an aggressive irrigation and débridement, especially over the metacarpophalangeal joint, and then referring. Ideally, tendon, bone, and joint tissues are kept moist in the wound with a damp sterile dressing to protect against desiccation of these vulnerable

Extensor tendon lacerations to the feet occur less frequently than in the upper extremities because of activity patterns and the protection that shoes and pants can provide. However, when these injuries do occur, they commonly are associated with additional significant trauma to other tissues, including fractures. The clinician must be diligent to rule out other possible injuries by considering associated anatomic structures and obtaining appropriate radiographs. Isolated lower extremity extensor tendon injuries otherwise might be managed in a similar fashion to upper extremity injuries, taking into account the correlating anatomic zones (e.g., a tendon injury at the ankle under the retinacular tissues would correlate to a zone VII injury in the upper extremity). Foot flexor tendons should be addressed by a clinician skilled in these areas. (It is not uncommon for an isolated flexor tendon laceration to be relatively well tolerated without repair.)

Clinicians normally will give an appropriately dosed first- or second-generation cephalosporin for a clean open injury, which should provide satisfactory coverage for most gram-positive skin organisms. Consideration for gram-negative and anaerobic coverage should be entertained for contaminated wounds, especially if occurring at a farm. *Pseudomonas* coverage usually is wise for foot lacerations. Continued antibiotics are typically unnecessary unless there is gross contamination or a subsequent infection develops. It is safest to reevaluate these wounds and repairs 2 to 3 days later for possible early infection. Adjustment of antibiotic management might be necessary, especially when considering the patient's particular circumstances.

#### **PATIENT EDUCATION GUIDES**

See patient education and patient consent forms available online at www.expertconsult.com.

# **CPT/BILLING CODES**

- 25270 Repair, tendon or muscle, extensor, forearm and/or wrist; primary, single, each tendon or muscle
- 25272 Repair, tendon or muscle, extensor, forearm and/or wrist; secondary, single, each tendon or muscle
- 26410 Repair, extensor tendon, hand, primary or secondary; without free graft, each tendon
- 26418 Repair, extensor tendon, finger, primary or secondary; without free graft, each tendon
- 26432 Closed treatment of distal extensor tendon insertion, with or without percutaneous pinning (e.g., mallet finger)
- 28208 Repair, tendon, extensor, foot; primary or secondary, each tendon

# **ICD-9-CM DIAGNOSTIC CODES**

- 727.63 Rupture of tendon, nontraumatic, extensor tendons of hand and wrist
- 727.68 Rupture of tendon, nontraumatic, other tendons of foot and ankle
- 736.1 Other acquired deformities of limbs, mallet finger

- 882.2 Open wound of hand except fingers(s) alone, with tendon involvement
- 883.2 Open wound of fingers(s) with tendon involvement
- 892.2 Open wound of foot except toe(s) alone with tendon involvement
- 893.2 Open wound of toe(s) with tendon involvement

#### **ACKNOWLEDGMENT**

Thanks for the many contributions of Thomas J. Zuber, MD, and John L. Pfenninger, MD, to this chapter in a previous edition of this text.

# FRACTURE CARE\*

Robert L. Kalb • Grant C. Fowler

Primary care clinicians are able to manage a wide range of fractures with good outcomes. To do this optimally, however, it is important to have adequate orthopedic training (perhaps on a rotation in residency), as well as supportive orthopedic backup. In fact, primary care clinicians so equipped can manage more complicated fractures, including about a third of fractures requiring reduction. A patient with multiple fractures or open, displaced, intra-articular, or epiphyseal plate fractures should generally be referred to an orthopedic surgeon. Adverse outcomes can be avoided by carefully choosing which fractures primary care clinicians manage, based on their level of training or appropriate consultation. This chapter provides guidelines for the office, urgent care, and emergency center management of fractures by the primary care clinician.

Decisions regarding whether to manage a displaced fracture are often influenced by the state's malpractice climate, insurance carriers, and premiums. Managing fractures requiring reduction often necessitates a higher level of malpractice coverage and higher premiums. Those clinicians treating fractures, especially fractures that require reduction, must have a good working relationship with an orthopedic surgeon willing to provide informal advice on management and on specific cases. It is ideal to have a relationship with an orthopedist who is able occasionally to examine a patient and return the patient to the referring clinician for follow-up care.

All of the fractures discussed in this chapter can be treated by the primary care clinician, with or without local anesthesia. This chapter is intended to serve as a guide or a basic summary for primary care; it cannot possibly review the management of all fractures. Because the management of fractures in children often differs greatly from that of fractures in adults, children are considered separately.

With all fractures, healing starts when osteoclasts arrive at the fracture site, causing resorption of the dead, soon to be demineralized bone. This resorption results in the fracture line appearing larger in the follow-up radiograph (even in those fractures that are nondisplaced or initially have only hairline cracks). As the fracture heals further, callus forms and the pain and tenderness decrease. However, the radiograph will not show callus and healing until later, when it has mineralized. It is only when mineralization has occurred that the x-ray beam no longer easily penetrates the callus, which results in the image of healing observed on the radiograph.

Box 190-1 lists types of casts. Chapter 186, Ankle and Foot Splinting, Casting, and Taping, and Chapter 187, Cast Immobilization and Upper Extremity Splinting, contain more details on casts than are discussed in this chapter.

# **EQUIPMENT**

See the discussions of equipment in Chapter 186, Ankle and Foot Splinting, Casting, and Taping, and Chapter 187, Cast Immobilization and Upper Extremity Splinting.

#### **TERMINOLOGY**

Open fracture: This fracture communicates through a hole in the skin; therefore, by definition, an open fracture is contaminated and is more likely to become infected, especially if the hole is greater than 1 cm in diameter. Open fractures should almost always be referred to an orthopedic surgeon. (Previously, the term compound fracture was used to describe an open fracture.)

Closed fracture: This fracture is not openly communicating through a hole in the skin. The vast majority of fractures are closed, and the skin is unbroken.

Torus fracture: In this fracture only one of the cortices is buckled. Greenstick fracture: A greenstick fracture is a level worse than a torus fracture. It involves an actual crack or disruption of one cortex and buckling of the opposite cortex. This fracture is so named because the bony deformation is much like that seen after cracking a green tree twig in springtime: the tension side of the bent twig cracks, whereas the compression side (i.e., the concave side) merely buckles.

Comminuted fracture: In this fracture the bone is in more than two pieces. Often an additional piece, which is small and shaped like a butterfly and therefore named a butterfly fragment, is found at the fracture site.

Fracture dislocation: A joint is dislocated and associated with a bony fracture on one or both sides of the joint.

Intra-articular fracture: This fracture extends into the joint or articular surface. If an intra-articular fracture is displaced, the patient should be referred to an orthopedic surgeon.

Delayed union: Delayed union occurs when a fracture is not healed after a time interval that is twice the normal healing time. For example, a fracture of the radius would be considered a delayed union if it has not healed in 4 months because it has an expected healing time of 2 months.

Nonunion: The bone has not united after three times the normal healing time. For example, a distal radius fracture is expected to heal completely in 2 months. If it has not healed in three times that amount, or 6 months, it is considered a nonunion fracture.

Atrophic nonunion: A bone end near the fracture becomes pointed like a partially consumed peppermint stick or icicle without any sign of new bone formation.

Hypertrophic nonunion: The bone end forms new bone even though it is not united.

*Malunion:* A fracture has united with unacceptable angulation, rotation, or shortening.

# FRACTURES IN ADULTS

# **Cervical Spine Fracture**

The possibility of a cervical spine fracture being unstable with associated spinal cord complications should always be considered (in fact, most are unstable). The exceptions would be a certain spinous process fracture (clay shoveler's fracture) or a simple anterior wedge fracture (defined as <25% loss of vertebral body height and no

<sup>\*</sup>Also see Chapter 231, Principles of X-Ray Interpretation.

# Box 190-1. Types of Casts\*

Long-arm cast (see Fig. 187-7): Always begins at the level of the proximal palmar crease and ends at the upper two thirds of the humerus. It always holds the elbow in 90 degrees of flexion. It begins as a short-arm cast and is then extended in a second stage.

Short-arm cast (see Fig. 187-4): Always begins at the proximal palmar crease and ends just below the elbow crease. Short-leg cast (see Fig. 187-5): Always begins at the tips of the toes with the ankle in a neutral position and extends up to just behind the knee, allowing the patient to bend the knee at least 90 degrees without pinching from the

Long-leg cast (see Fig. 187-7F): Always extends from the tips of the toes up to the proximal thigh. A long-leg cast is always a combination of first applying the short-leg cast and then extending it into a long-leg cast as the second stage, just as for a long-arm cast application.

If the knee is in approximately 30 degrees of flexion, crutch walking is easier because the foot is out of the way on the non–weight-bearing side. The 30 degrees of flexion helps control rotation of the tibia and ankle; it also prevents the patient from walking on the cast. Without 30 degrees of flexion, no rotational control is present.

\*See Chapter 187, Cast Immobilization and Upper Extremity Splinting.

subluxation on dynamic flexion-extension radiographs of the cervical spine). The clay shoveler's fracture is an avulsion of the tip of the spinous process of C6 or C7 due to stress on the interspinous ligaments. These cervical fractures require nothing more than a soft cervical collar and symptomatic management.

All patients with a suspected cervical spine fracture should have a three-view series of cervical spine radiographs: cross-table lateral, anteroposterior (AP), and open-mouth odontoid views. In most cases, the lateral view should be taken first to rule out an occult fracture before the neck is moved. Overall, this view provides 90% of the information regarding the stability of the spine. The radiologist, neurosurgeon, or orthopedist can review the radiographs to exclude any associated problems. It should be noted that even minor fractures seen on plain radiographs may be associated with significant ligamentous injuries that render the cervical spine unstable; consultation with a neurosurgeon or orthopedist is helpful.

## **Thoracolumbar Spine Fractures**

A thoracolumbar spine fracture can generally be treated with symptomatic management, brief (24 to 48 hours) bed rest with serial neurologic monitoring, followed by back support (thoracolumbosacral orthosis [TLSO]) and rehabilitative exercises. Exceptions include evidence of instability such as loss of greater than 50% of the anterior vertebral height (compared with posterior vertebral body height), presence of more than 20 degrees of angulation, an increased space between the spinous processes, and disruption of the facet joints; these patients should generally be referred. Burst fractures or fractures associated with any sign of neurologic injury should also be referred for orthopedic or neurosurgical consultation to rule out instability (which may require surgical stabilization). An exception to the use of a TLSO is a compression fracture occurring in an osteoporotic patient; in such cases, a TLSO is usually unnecessary and may impair return to function in the elderly.

Fractures of the upper thoracic spine (T1 to T9) tend to be more stable because of attachments of the rib cage, which in turn are

further stabilized at the sternum. Fractures of L2 to L5 tend to be more stable because of the larger vertebral bodies; fractures of L5 and S1 tend to be unstable because of the high-energy forces required to cause injury at this level. Transverse process fractures, usually at L2, L3, or L4, and spinous process fractures are usually benign and do not affect spine stability. With a transverse or spinous process fracture in the general region of the kidneys, the possibility of a renal contusion should be considered.

For possible thoracolumbar spine fractures, radiographs should include AP, lateral, and oblique views of the entire thoracolumbar spine (patients often have fractures at more than one level). When managing a compression fracture, serial radiographs should be obtained at 3, 6, and 12 weeks to rule out a progressive kyphotic deformity (>20 degrees of angulation). Computed tomography (CT) scanning is particularly helpful in diagnosing multiple or occult fractures or bony impingement on the spinal canal. Magnetic resonance imaging (MRI) is useful for evaluating soft tissue injury. When managing these fractures, an accompanying ileus is fairly common. Always consider radiographs of the lumbar spine in a patient who has a calcaneal fracture because the axial loading associated with such an injury is often associated with a lumbar spine fracture.

#### **Pelvic Fractures**

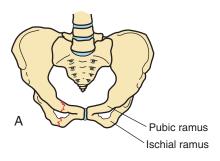

Pelvic fractures managed by primary care clinicians tend to occur in osteoporotic older patients due to a fall. Otherwise, pelvic fractures are usually the result of significant trauma in a motor vehicle accident or a fall from a considerable height. Most fractures of the pelvis are diagnosed on the AP view. Additional views to assess the pelvis include inlet, outlet, and oblique views of the acetabulum. If there is concern for acetabular involvement, obturator (45 degrees of internal rotation) and iliac (45 degrees of external rotation) oblique views should be obtained; a radiologist or orthopedist will usually be able to determine from these views whether any question remains of acetabular involvement. If the acetabulum is involved, the patient should generally be referred to an orthopedist. If comminution is present, CT can be used for further delineation. Orthopedic referral should also be considered if the pelvic ring is unstable. However, there must be two breaks in the pelvic ring, either from two fractures or a fracture plus a joint dislocation (usually the sacroiliac joint), for a pelvic fracture to be unstable. Fractures external to the pelvic ring are generally considered stable (Fig. 190-1).

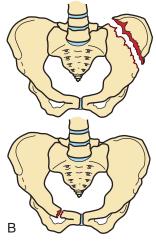

If the pelvic fracture is considered stable, the patient can be treated with bed rest, analgesics, walking as tolerated, or full weight bearing with a walker. The pubic and ischial rami function only as tie rods for the anterior portions of the pelvis; they are not weight bearing. The typical older woman who falls and breaks her pelvis has a pubic or ischial ramus fracture only (see Fig. 190-1) and does not require either surgical intervention or bed rest. Otherwise, the length of bed rest is variable, usually from 2 to 4 weeks; the patient may sit as tolerated. During bed rest, gentle range of motion exercises of the lower extremities should be performed, especially in the elderly. Although walking may be uncomfortable, explain to the patient that it is not dangerous or harmful.

If the pelvic fracture occurs in an individual younger than 50 years of age or one involved in a motor vehicle accident, be prepared to resuscitate the patient because hemorrhagic shock is the major cause of death. Consider the possibility of bladder, urethral, or external genitalia injury, especially with anterior pelvic fractures and especially in men. Always palpate the sacroiliac joint to ensure that it is nontender and therefore not involved in the injury.

# Intertrochanteric Femur Fracture

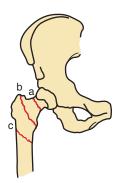

The intertrochanteric femur fracture (Fig. 190-2) is the most common type of hip fracture. Occurring between the greater and lesser trochanter of the proximal femur, this fracture does not

**Figure 190-1** Stable pelvic fractures. **A,** Nonsdisplaced ramus fractures. **B,** Fracture of the pelvis not involving the ring (*top*). Stable, minimally displaced fracture of the ring (*bottom*).

involve the hip joint itself; it is an extra-articular, extracapsular fracture. The patient typically presents with a markedly shortened and externally rotated leg, painful with any movement of the hip. An intertrochanteric fracture usually results from the patient tripping over a carpet, pet, or step or slipping and falling; the force of the direct fall onto the intertrochanteric area causes the fracture. This scenario is entirely different from the femoral neck stress fracture discussed next. Repair of the intertrochanteric fracture requires hip pinning with a compression screw. It may require open reduction with use of a bone plate device to achieve near-anatomic alignment. Without repair, the intertrochanteric fracture, even if nondisplaced, is at high risk for displacement with such minor activities as rolling over or moving in bed. Therefore, if possible, these patients should be referred to an orthopedist for surgical repair. In the nonambulatory patient, such as the nursing home patient, nonoperative treatment may be a safer and less costly alternative. The patient should

**Figure 190-2** Fractures of the proximal femur: Neck (a); intertrochanteric (b); subtrochanteric (c).

be managed symptomatically; Buck's traction can be used intermittently to reduce pain. The patient should be mobilized to a sitting position within 2 to 3 days. Nonoperative treatment for the ambulatory patient is a rare possibility; it is beyond the scope of this chapter.

#### **Femoral Neck Fracture**

Fracture of the femoral neck (see Fig. 190-2) is the second most common type of hip fracture. For a younger person to sustain a femoral neck fracture from trauma takes signficant force; therefore, most of these fractures occur in older osteoporotic patients, often while just walking in the home. The hip suddenly gives way, and the patient falls to the floor; no history of tripping over a carpet, pet, or step is usually reported and the patient does not know the reason for the fall. In most cases, an osteoporotic femoral neck fracture is actually a stress fracture, which ultimately becomes complete. As the fracture completes itself, it results in the instability that causes the patient to fall. Most of these fractures are displaced; therefore, appropriate treatment is prosthetic replacement (one half of a total hip). Occasionally, these fractures are nondisplaced and can be treated with pinning. Because the femoral neck (most of it) is intracapsular, the greater the displacement, the greater the risk of vascular compromise. Because of this tenuous blood supply, all femoral neck fractures should be monitored for the development of avascular necrosis, even if a prosthesis is placed.

If a patient does not have a history of falling but complains of pain in the groin aggravated by walking and weight bearing, rule out hip osteoarthritis with a weight-bearing radiograph. Always be certain to order a true lateral radiograph of the hip because it will often show a fracture not visible on the plain AP or "frog leg" AP view. If the hip joint is free of osteoarthritic findings, a diagnosis of impending stress fracture should be considered. In some patients, the fracture is not visible on the radiograph but can be observed on limited MRI. MRI is now considered the standard of care because it is more sensitive and specific than either a bone or CT scan for diagnosing femoral neck stress fractures. Nonathletes with nondisplaced stress fractures in progress demonstrated by bone scan or MRI can be treated with a walker and no weight bearing on the involved side. This treatment often allows the fracture to heal completely and prevents surgery.

Femoral neck stress fractures can also occur in athletes, and inguinal or anterior groin pain is the most frequent symptom. If the diagnosis is delayed, night pain can occur. On physical examination, discomfort is noted at the extremes of internal and external rotation, especially internal rotation. Compression-type stress fractures occur on the inferior medial border of the femoral neck and are considered more stable; tension-type stress fractures occur on the superior lateral border, are less stable, and are more prone to dislocate. Patients with an overt fracture line should be referred to an orthopedist. Conservative treatment consists of modified bed rest followed by assisted crutch-walking as tolerated until healing is seen (usually 6 weeks); cross-training with cycling or swimming will be helpful for maintaining fitness. Serial radiographs should be obtained every 1 to 2 weeks for the first month or at any time the patient stops improving; if sclerosis extends through both cortices or a crack develops, the patient should be referred. If the patient fails to heal with non-weight-bearing, he or she should be referred to an orthopedist. Otherwise, after 6 weeks, weight-bearing exercise can be resumed to preinjury levels over a span of 6 to 8 weeks; the patient should be able to walk a mile without pain before any running is allowed.

#### **Femoral Shaft Fracture**

Femoral shaft stress fractures can also occur in athletes. Lacking a history of trauma, the athlete often presents with vague thigh pain, diffuse tenderness, and a suspected quadriceps strain. These patients

frequently wait 4 to 6 weeks following the onset of symptoms before seeking care; persistent, worsening symptoms finally bring them in. Fortunately, most femoral shaft stress fractures do not progress to complete fractures. Conservative care consists of relative rest with a switch to non-weight-bearing activities such as swimming or cycling for 6 to 8 weeks. Serial radiographs should be obtained and results managed as for a femoral neck stress fracture. Return to full activity can usually be anticipated after 3 to 4 months.

Other than stable stress fractures, femoral shaft fractures should always be referred for surgical stabilization. These fractures are at high risk for fat embolism and neurovascular problems. A distal femur fracture, which is often intra-articular (extending into the knee joint), should usually undergo surgery to stabilize the fracture, even if the fracture is nondisplaced.

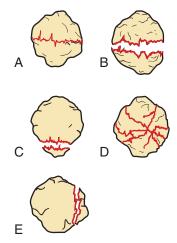

#### **Patellar Fractures**

If the articular surface is smooth and the quadriceps mechanism intact, a nondisplaced patellar fracture (Fig. 190-3), whether comminuted or not, can be treated with a cylinder (from above malleoli to groin), full weight-bearing walking cast or with a knee immobilizer (in a reliable patient), crutches, and 10% partial weight-bearing activities. Consider referring severely comminuted fractures or fractures with more than 3 mm separation or more than 2 mm articular step-off to an orthopedist. Otherwise, a follow-up clinical examination is performed and AP and lateral radiographs assessed 3 weeks after initial treatment. If no displacement exists and tenderness with palpation is resolved, then gentle non-weight-bearing range of motion exercises can be started in an arc of 0 to 45 degrees. Another radiograph should be obtained 6 weeks after treatment; at this point, the fracture should be solidly healed and point tenderness over the patella resolved. Active and passive range of motion activities can now be initiated in therapy. During the healing phase, the patient should be encouraged to carry out quadriceps and hamstring isometric and straight-leg raising exercises to maintain muscle function and tone.

Marginal vertical fractures that are nondisplaced do not have to be immobilized. They can be treated with reduced activity for 4 to 6 weeks followed by progressive range of motion and strengthening evertices.

#### **Tibial Plateau Fractures**

The clinician should be certain that a tibial plateau fracture is not depressed or displaced, especially if it extends into the joint surface. Lateral, AP, and internal and external oblique radiographs should

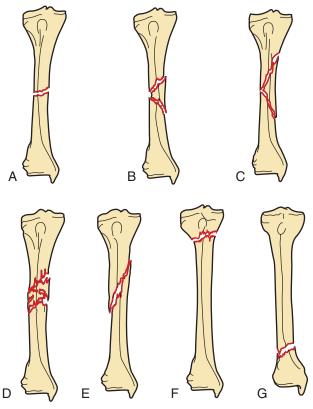

**Figure 190-3** Classification of patellar fractures. **A,** Nondisplaced transverse. **B,** Displaced transverse. **C,** Upper or lower pole. **D,** Comminuted. **E,** Vertical.

be obtained. A tunnel (notch) view is helpful for visualizing the intercondylar eminence. Tomograms are the only method to exclude displacement. CT will help delineate the extent of articular involvement and fracture displacement; MRI also provides this information and can detect ligamentous and meniscal injuries. If any depression or displacement has occurred, the patient must be referred; fractures associated with ligamentous or meniscal injury should also be referred. These referrals should generally occur within 24 to 48 hours.

If the fracture is extra-articularly displaced (intra-articularly nondisplaced), it can be treated with crutches, non-weight-bearing activities for 3 months, and gentle range of motion activities. Otherwise, the patient should remain non-weight-bearing for 4 to 6 weeks, until there is radiographic evidence of healing, and can then progress to partial weight bearing with crutches. Crutches should be used until solid union of the fracture is documented. These fractures need to be watched carefully with clinical examination and radiographs at 2-week intervals for the first month to be certain there is no displacement, which can occur with motion of the knee joint. Be certain to document the strength of the peroneal nerve.

#### **Tibial Shaft Fractures**

Tibial shaft fractures (Fig. 190-4) can be treated with a long-leg cast with the knee in 0 to 5 degrees of flexion and the ankle in neutral position (90 degrees). The patient can bear weight with this cast, and ambulation should be encouraged as soon as possible (as long as there is no risk for compartment syndrome [see Chapter 188, Compartment Syndrome Evaluation], which can occur at up to 10 days). As it turns out, most patients are not able to bear significant weight, due to discomfort, for 1 to 2 weeks.

**Figure 190-4** Tibial shaft fractures. **A,** Transverse or short oblique. **B,** Small butterfly fragment. **C,** Large butterfly fragment. **D,** Segmental comminution. **E,** Spiral. **F,** Proximal one fourth transverse or oblique. **G,** Distal one fourth transverse or oblique. The fracture in **A** is usually stable. The stability of the fractures shown in **B** and **C** is dependent on the size of the butterfly fragment. The fracture shown in **D** is usually unstable. The fractures shown in **E-G** are stable but difficult to control.

Proximal shaft fractures are often due to high-energy forces, but distal fractures are usually the result of low-energy injuries; this concept is important to consider during management. There should be less than 5 mm of *displacement* in both the AP and mediolateral planes; otherwise, the patient should be referred. If any *angulation* of the tibial shaft fracture has occurred, a *goniometer* must be used to assess the amount. Angulation up to 10 degrees in the AP radiograph and up to 5 degrees in the mediolateral plane is acceptable. Angulation greater than these amounts requires correction by wedging the cast; these patients should be referred.

If less than 50% bone surface contact between fracture fragments is observed in the AP or lateral views, then the patient should be referred to an orthopedic surgeon. Degree of rotation should be determined by the amount of discrepancy between transverse widths of the proximal and distal fragments; greater than 10 degrees of rotation should also be referred. Shortening greater than 2 cm is not acceptable and requires referral. If any doubt remains about the amount of overlap (which causes shortening), a bone length measurement radiograph can be obtained for the radiologist to compare the length of one tibia with the other.

For tibial fractures in which the fibula is not broken, very little chance exists of the tibia becoming unacceptably shortened because the fibula will splint the soft tissue at an appropriate length. If the fibula is broken in addition to the tibia, a higher incidence of shortening of the tibia exists as a result of unopposed muscle contraction. This is especially true in an oblique angle fracture; the oblique angle allows sliding of the fracture into a shortened position. If the fracture is transverse, then this sliding shortening cannot occur. Nevertheless, combined tibia–fibular fractures are frequently due to high-impact forces, are at high risk for compartment syndrome, and are rarely nondisplaced; these patients are frequently referred.

If the fracture is satisfactory in alignment and length, then a long-leg cast for a period of 4 to 6 weeks is appropriate. For the initial cast, plaster is usually easier to mold; fiberglass reinforcement can then be applied in a few days if this cast is left in place. The cast will usually need to be changed in 2 to 3 weeks because of loosening as the swelling decreases. After 4 to 6 weeks, the cast can be cut down to a short-leg walking cast or a walking cast brace for an additional 10 to 14 weeks, until clinically healed. To verify clinical healing, there should be minimal tenderness over the fracture site and no motion or pain with bending stress in any direction.

Tibial fractures are notorious for developing compartment syndrome (see Chapter 188, Compartment Syndrome Evaluation) when any significant soft tissue trauma has occurred. If the tibial fracture is the result of a fall from a height greater than 6 feet or the result of a high-velocity injury such as in an automobile accident, be very cautious about the possibility of compartment syndrome. Be certain that the patient elevates the leg at home so that the calf is 2 feet higher than the heart at all times, except when going to the bathroom, for 1 week. Explain to the patient that the heart is the pump, and that the fluid from the leg needs to drain toward the pump, which requires the fluid in the leg to be elevated higher than the pump. Seat cushions from the couch stacked three high under the calf can help achieve this elevation. The patient's chest must be flat, although pillows can be placed under the head to facilitate reading and eating. Sitting in a recliner, however, does not provide adequate elevation because the chest is only at the level of the calf.

Patients at risk for compartment syndrome may use their crutches to go to the bathroom, placing no weight on the injured side. They should return to the bed, couch, or floor, lie down, and resume elevation of the leg as soon as possible. If there is loss of fine-touch sensation or two-point discrimination, distention and swelling of the calf, pain with passive motion of muscle groups (especially extension of the great toe), progressive pain, or pain not relieved by oral pain medication such as narcotics, then emergent testing should be performed or referral made to rule out compartment syndrome (see Chapter 188, Compartment Syndrome Evaluation). The peak

time for compartment syndrome after a tibial fracture is on the third day after the injury.

Tibial stress fractures are one of the most common stress fractures in young athletes and military recruits. They occur more commonly at the junction of the middle and distal thirds of the tibia in runners, in the middle third in ballet dancers, and in the proximal third in military recruits. Symptoms are usually insidious in onset, increase with physical activity, and may become severe enough to persist for hours after activity or even at night. There is usually pain with palpation but minimal swelling at the site of tenderness. However, pain can often be elicited at the site by applying a tuning fork or by percussing the tibia away from the site. Radiographs are frequently negative for 2 to 4 weeks after the onset of symptoms; a triple-phase bone scan can be helpful if a stress fracture is strongly suspected. Most tibial stress fractures are treated with elimination of impact activity for 4 to 6 weeks, cross-training, and crutches as needed for pain. Radiographs should be taken monthly to document healing.

Radiographs may demonstrate the "dreaded black line" fracture, which is an anterior midshaft tibial stress fracture associated with poor healing, a risk of nonunion, and risk of recurrence. These fractures typically take 6 to 12 months to heal; patients must refrain from impact loading activities until they are pain-free and there is complete radiographic healing.

#### Fibular Shaft Fractures

Fibular shaft fractures require no immobilization or restriction of weight-bearing activities, other than for pain management, because the fibula supports only 15% of the weight in the lower extremity. In fact, the fibula can be used elsewhere as a bone graft without a problem. Fibular fractures, however, rarely occur alone. Always check for associated injury around the ankle, over the medial and lateral collateral ligaments, and the tibiofibular distal joint. It is common for a severe ankle-twisting injury to result in a small fracture around the ankle and an associated fracture somewhere along the fibula, including the proximal fibula (Maisonneuve fracture). Isolated fibular fractures can occur from a direct blow to the side of the calf. Again, these fractures require no immobilization or restriction of weight-bearing activities and almost always heal uneventfully within 6 to 8 weeks. Use of a stirrup splint, a short-leg walking cast, or a cast boot for 3 to 4 weeks may help relieve moderate to severe pain.

Always evaluate the function of the peroneal nerve when treating a fibular fracture by documenting the strength of active foot flexion and extension at the ankle, as well as eversion. If the peroneal nerve is affected, document this and consider referral to an orthopedist. Also consider referral for severely displaced or comminuted fractures, ligament instability, or painful nonunion after treatment.

# **Ankle Fractures**

Point tenderness over the lateral malleolus (distal fibula) or medial malleolus (distal tibia) often indicates an ankle fracture as opposed to a sprain. The area of the posterior malleolus (distal tibia, immediately behind the medial malleolus) should also be palpated for tenderness. If no point tenderness is felt over the malleoli, then an x-ray is rarely necessary. This decision is supported by the Ottawa Ankle Rules, which indicate a radiograph is most predictive of fracture if the patient has pain over the malleolus and tenderness over the malleolus or the patient was unable to bear weight immediately at the time of injury and at the initial clinician visit. Point tenderness over the anterior and lateral ligaments (anterior talofibular and lateral calcaneofibular ligament), but not the fibula, indicates an ankle sprain. A first-degree ankle sprain will have tenderness only over the anterior talofibular ligament, whereas a second- or third-degree ankle sprain has tenderness over the talofibular and calcaneofibular ligaments.

If ankle radiographs are indicated, obtain lateral, AP, and mortise (AP view with the foot in 15 degrees of adduction) views. The ankle mortise is the joint space between the top of the talus and the bottom of the tibia, as well as the medial and lateral malleoli. There should be symmetrical spacing throughout the mortise; in other words, there should be less than 1 mm of displacement of the talus in any direction greater than elsewhere in the mortise. A nondisplaced fracture of the ankle is frequently seen in only one radiographic view of the ankle.

Small avulsion fractures, nondisplaced single malleolar fractures, and stable bimalleolar fractures can be treated nonoperatively. Small, nondisplaced avulsion fractures are treated with early mobilization and weight bearing, as tolerated, similar to an ankle sprain. A functional stirrup splint worn in a shoe may be adequate; functional rehabilitation exercises can be started as soon as symptoms allow. Unstable fractures (e.g., malleolar fracture with ligament disruption on the opposite side), displaced single malleolar, large (>25% of articular surface) or displaced (>2 mm) posterior malleolar, or trimalleolar (bilateral plus posterior malleolar) fractures (or if clinician is unsure about the stability of the fracture) should be referred. Otherwise, medial and lateral malleolar fractures require a minimum of 4 weeks for clinical healing and possibly several months for radiographic healing. When following an ankle fracture with radiographs, the mortise view should always be examined for evidence of new instability or a shift.

If the patient smokes, the fracture healing time can be doubled; it can also be delayed in patients who are taking anti-inflammatory medications. Patients should be informed that the incidence of *reflex sympathetic dystrophy* (see Complications section) after any injury in this area, including a fracture, is much higher when they smoke.

**NOTE:** A cast boot should be prescribed for any patient wearing a short-leg splint or cast or a long-leg splint or cast. The cast boot protects the toes and cast and prevents material from slipping through the end of the cast and up underneath the foot.

# Medial and Posterior Malleolar (Distal Tibia) Fractures

If an isolated medial or small (<25% of the articular surface) posterior malleolar fracture is shown to be nondisplaced in the lateral, AP, and mortise views of the ankle, treatment with a short-leg weight-bearing cast (or walking fracture boot in a trusted, compliant patient) is appropriate. (Suspect Maisonneuve fracture in isolated posterior malleolar fracture.) The ankle should be immobilized in the neutral (90 degrees) position to minimize Achilles tendon shortening. The patient should be seen again in 2 weeks to assess the condition of the cast (or compliance with the walking boot) and at 4 weeks to repeat radiographs. If the initial fracture line is below (distal to) the level of the ankle mortise, immediate full weightbearing activities may be allowed, as tolerated. If the fracture is at or above the ankle mortise, and at 4 weeks is clinically healing (nontender over the fracture site and some evidence of radiographic healing such as callus formation), the patient may begin gradual weight bearing and ankle rehabilitation. If no radiographic evidence of healing is apparent at 4 weeks, the patient should remain in the cast another 2 weeks and return for repeat radiographs. At that point, if the patient is still not clinically healed, a fracture boot should be worn, and walking and ankle rehabilitation initiated.

# Lateral Malleolar (Distal Fibula) Fractures

There are three types of fractures in the distal third of the fibula. Because these fractures can be associated with a medial ligament injury and subsequent instability, repeat radiographs should be obtained in 7 to 10 days to assess fracture alignment and the position of the mortise. A *Weber A* fracture occurs below the level of the ankle mortise and can be treated with an immediate weight-bearing

short-leg cast or fracture boot for 6 weeks. A *Weber B* fracture occurs at the level of the ankle mortise. Again, if the lateral, AP, and mortise x-ray views show the fracture to be nondisplaced, it can be treated with a short-leg walking cast for 6 weeks. Because this fracture is at the level of the ankle mortise, weight bearing should not be allowed for the first 2 weeks. This restriction decreases stress at the ankle mortise, which could cause displacement at the fracture site. A *Weber C* distal fibular fracture occurs above the ankle mortise and has the greatest potential for displacement. This fracture disrupts a portion of the syndesmotic ligament area between the tibia and fibula distally, just above the ankle mortise. This fracture is also treated in a walking cast for 6 weeks with no weight bearing during the first 3 weeks.

# Talar Fractures

Minor anterior and posterior avulsion fractures of the talus are occasionally seen in association with ankle injuries. Lateral avulsion fractures, just distal to the tip of the distal fibula, are occasionally seen in snowboarders (snowboarder's fracture) and can be large and comminuted. Small (<0.5 cm), nondisplaced, anterior and posterior avulsion fractures are treated with a short-leg walking cast for 1 month followed by range of motion, stretching, and strengthening rehabilitation exercises. Anterior avulsion fractures should be cast with the ankle in the neutral position (90 degrees); posterior avulsion fractures benefit from being cast in 15 degrees of equinus (plantar flexion), which allows tiptoe weight bearing. Small (<2 mm), nondisplaced, noncomminuted lateral avulsion fractures are probably best managed in a short-leg, non-weight-bearing cast for 4 weeks followed by 2 weeks of progressive weight bearing in a walking cast or cast boot. If displacement has occurred for an avulsion fracture, or the fragment is large or comminuted, the patient should be referred to an orthopedic surgeon.

Prolonged pain (several weeks to months) following an inversion injury of the ankle, often associated with point tenderness in the area, decreased range of motion, crepitus, and an effusion, should lead the clinician to suspect an osteochondral talar dome fracture. If plain films show no abnormality, a bone scan is highly effective for detecting these fractures. For positive bone scans, an MRI is effective at determining the exact location and stage. Symptomatic stage I (compressed, nondisplaced) and stage II (attached, nondisplaced) osteochondral talar dome fractures typically respond well to conservative treatment with immobilization for 6 to 8 weeks in a non-weight-bearing cast followed by rehabilitation; referral should be considered if symptoms persist after 4 to 6 months of conservative therapy. Stage III (detached, nondisplaced) and stage IV (displaced) talar dome fractures are best treated with early operative care (often just arthroscopy). Talar head fractures can be treated with a shortleg walking cast for 6 to 8 weeks followed by longitudinal arch support for several more weeks. Patients should be warned that this fracture may be complicated by persistent pain due to post-traumatic arthritis in the talonavicular joint.

The patient should be aware that despite perfect reduction, healing is often complicated by avascular necrosis in fractures of the talar neck and body. The nonunion rate may be as high as 50%, and there is an associated high incidence of osteoarthritis. Talar fractures are second only to scaphoid (navicular) fractures in the wrist as a site for chronic postfracture complications and pain. That said, nondisplaced talar neck fractures can be treated with a non-weightbearing short-leg cast for 4 to 6 weeks followed by a short-leg walking cast for an additional 4 weeks. If there is no radiographic evidence of fracture union at 6 weeks, radiographs should be repeated every 2 to 3 weeks and the patient should remain in a walking cast until union is documented. CT scanning may be necessary to demonstrate fracture union. Nondisplaced talar body fractures should be immobilized in a short-leg non-weight-bearing cast for 6 to 8 weeks. All patients with a talar fracture should be instructed in range of motion, stretching, and strengthening rehabilitation exercises following cast removal. Patients should be seen 2 to 3 weeks into such a rehabilitation program and then followed until there is near-normal function.

#### **Calcaneal Fractures**

Obtain axial, lateral, and dorsoplantar radiographs of the calcaneus for suspected fractures. Comparison views of the opposite side may be helpful for diagnosing bilateral fractures (common) as well as for measuring anatomic angles. Oblique views may also be helpful. If any doubt remains about displacement, obtain a CT scan. A radiologist or orthopedist can offer suggestions about the need to obtain a CT scan after viewing the plain radiographs. Intra-articular (subtalar joint) fractures (approximately 70% of calcaneal fractures) or displaced extra-articular fractures should generally be referred to an orthopedist.

If the vertical forces were significant enough to cause a calcaneal fracture (e.g., a fall from a height), a radiograph of the thoracic and lumbar spine should also be obtained; there is a high incidence of associated axial fractures (e.g., thoracic and lumbar spine fractures). The clinician must also palpate the thoracic and lumbar spine for signs of tenderness in these patients.

For a nonarticular, nondisplaced fracture of the calcaneal body, pain management, treatment with a bulky compression soft wrap, and elevation are all that is needed. These fractures generally heal well regardless of treatment. Early, gentle, yet active range of motion exercises of the foot and ankle are appropriate to minimize the stiffness associated with these fractures. Maximal elevation is critical to minimize swelling and pain; swelling can be significant, even causing blisters or skin loss with subsequent infection. Elevation with the patient lying down and the hip and knee both flexed to 90 degrees with couch cushions under the calf is the best management for the first week. Patients may be up on crutches only to go to the bathroom; otherwise, they should be supine with the leg elevated.

**AUTHOR'S NOTE:** If the patient is not instructed to keep the hip and knee bent 90 degrees with elevation, he or she may complain of sciatica. When pillows or blankets are placed only underneath the heel, the knee remains straight and can result in the sciatic nerve being stretched.

For extra-articular fractures of the anterior, medial, or lateral calcaneal processes, the patient should be placed in a short-leg walking cast for 4 weeks. Fractures of the tuberosity or sustentaculum tali should be managed with a short-leg non-weight-bearing cast for 6 to 8 weeks. Tuberosity fractures should be cast in 5 to 10 degrees of equinus (plantar flexion) and repeat radiographs obtained at 1 week to check for alignment. The patient should be seen every 2 to 4 weeks for management of all of these fractures.

# Midfoot Tarsal Bone (Cuneiforms, Cuboid, and Navicular) Fractures

Lateral, AP, and oblique radiographs should be obtained for suspected midfoot fractures. For nondisplaced fractures, apply a short-leg walking cast for weight-bearing activities as tolerated after the first week. For most, the cast should be in place for 4 to 6 weeks; fractures of the navicular body may benefit from casting for 8 weeks total. For nonunion of a navicular tuberosity fracture, 8 to 10 weeks of casting may be necessary. If fractures are displaced, severely comminuted, or there is nonunion of the navicular tuberosity after 10 weeks, or if there is a concomitant joint dislocation, refer the patient to an orthopedic surgeon.

Beware of a fracture or dislocation of the *Lisfranc joint*, which extends into the tarsometatarsal joint at the midfoot and occurs when an athlete falls forward on a plantar-flexed foot. To prevent future disability, it is critical to diagnose an unstable fracture of this area, so always obtain routine as well as weight-bearing lateral and

AP radiographs for injuries to the bridge of the foot. Also suspect a Lis-franc injury when there is an avulsion "fleck" fracture of the lateral proximal first metatarsal or the medial proximal second metatarsal. The joint may appear nondislocated on the AP view; however, on the lateral view, anterior displacement may be observed. On the weight-bearing AP radiograph, widening may appear between the first and second metatarsals; on the weight-bearing lateral radiograph, a stepoff (evidence of joint disruption) between the tarsal and proximal metatarsal may appear. A CT scan can be used to confirm the diagnosis. If any questions remain about an injury to the midfoot or about the radiographic views, ask a radiologist or orthopedic surgeon to review the films. These fractures are rare because of the rigidity of the midfoot.

#### **Metatarsal Fractures**

The most common metatarsal fracture is at the base of the fifth metatarsal, and represents an avulsion fracture of the styloid where the peroneus brevis tendon inserts. With an inversion sprain-type injury to the forefoot and ankle, a small piece of bone can be pulled loose. The displacement is usually no greater than 3 mm; it is treated with a firm or wooden-soled fracture shoe with weight bearing as tolerated, and ice and elevation for comfort. The purpose of the wooden-soled shoe is to prevent flexion at the midfoot when the patient walks, thereby preventing stress at the fracture site. The wooden-soled shoe is worn for 3 weeks or longer until the patient is comfortable without it and can return to wearing a regular shoe. However, impact sports should be avoided for a minimum of 2 months.

A metatarsal avulsion fracture must be differentiated from a *Jones fracture*, which is much less common and treated entirely differently. A Jones fracture occurs in nearly the same location; however, it extends (if not initially, eventually) across the entire shaft just distal to the base of the fifth metatarsal and into the joint between the bases of the fourth and fifth metatarsals. If the fracture is displaced, the patient should be referred to an orthopedic surgeon. If nondisplaced, treatment includes a short-leg walking cast for 6 to 8 weeks with no weight bearing for the first 3 weeks. At this point, if neither clinical nor radiographic healing is apparent, a non-weight-bearing cast should be reapplied for 4 more weeks or the patient referred. This fracture is notorious for delayed union, especially in patients who smoke or take anti-inflammatory medications. No impact sports should be allowed after this injury for a minimum of 3 months.

A stress fracture of the fifth metatarsal can be confused with a Jones fracture, but it typically occurs in the proximal shaft. This fracture is also notoriously slow to heal. Although referral is not necessary in every case, referral should be considered because optimal conditions may require up to 20 weeks of immobilization and nonunion may still occur. With intramedullary screw fixation, the athlete may return to his or her sport much earlier. Stress fractures of the other metatarsal shafts are much more common and usually less severe. Symptoms may precede radiographic findings by 2 to 3 weeks. In most cases, these fractures can be managed without casting; merely eliminating impact (e.g., running, jumping) until clinical healing is documented is sufficient.

Nondisplaced fractures of metatarsal shafts can be treated with wooden-soled shoes. If there is significant pain (e.g., first metatarsal, multiple fractures), the patient can be in a short-leg walking cast for 4 to 7 weeks and minimize weight bearing for the first 2 to 3 weeks. Most displaced fractures of the first metatarsal should be referred. Patients with displaced fractures of multiple metatarsals, displaced fractures close to the metatarsal heads, and intra-articular fractures are probably best referred for pin fixation. Otherwise, fractures of the second through fourth metatarsals that are displaced only in the lateral or medial plane do not usually require reduction. Fractures of the second through fourth metatarsal shafts displaced more than 3 or 4 mm or angulated greater than 10 degrees in the dorsal or plantar plane should be reduced or referred. These fractures

can often be reduced under local anesthesia hematoma block using Chinese finger (toe) traps and gravity or 2 to 5 lb of weight. After reduction, a short-leg walking cast can be used for 5 to 7 weeks with no weight bearing the first 2 to 3 weeks.

Although rare, clinicians must beware of *compartment syndrome* in the foot. This can occur with multiple fractures (e.g., three or more metatarsals) from a crushing-type injury, and resultant extreme swelling.

#### **Toe Fractures**

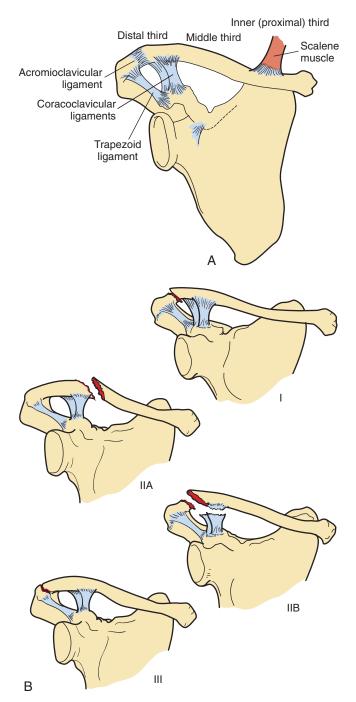

For the great toe, displaced intra-articular fractures and fractures that spontaneously become displaced when traction is released after reduction may benefit from internal fixation, so these patients should generally be referred. For the other toes, fracture dislocations and intra-articular fractures that involve more than 25% of the joint surface may benefit from referral. Otherwise, rarely is a surgical intervention required. Displaced fractures can be managed by reduction under digital block anesthesia followed by manual traction, pulling the toe into a corrected position. Many authorities recommend a short-leg walking cast with a toe platform for 2 to 3 weeks for fractures of the great toe followed by buddy taping and a woodensoled shoe. For fractures of other toes, buddy taping to an adjacent toe for 3 to 6 weeks will stabilize the fracture. Use of wooden-soled shoes for 2 to 3 weeks, ice, and elevation may decrease pain. When taping digits together (fingers or toes), place dry cotton or gauze between them to prevent skin maceration from moisture. Patients can change this dressing after a shower and watch the alignment of the nail beds for development of a rotational deformity, which can be surgically repaired. Patients should be followed by the clinician every 2 to 4 weeks. Follow-up radiographs are generally not needed except for fractures of the great toe or intra-articular fractures.

Fractures in the distal phalanges of the fingers or toes sometimes involve injury to the nail bed or an open fracture caused by the bone pushing up through the nail bed. In these patients, the treatment should be digital block anesthesia followed by removal of the nail to irrigate the nail bed thoroughly at the site of the open fracture. The nail bed can be repaired with 5-0 absorbable suture, which will minimize nail deformity. Nail bed repair is usually more desirable for the fingers because many individuals will accept deformity of a nail plate in a toe but are concerned about a cosmetic deformity in a finger (see Chapter 27, Nail Bed Repair).

#### **Clavicle Fractures**

Because outcomes are basically the same, treatment for fractures of the clavicle is generally whatever best relieves the symptoms. Possibilities include a figure-eight brace or sling, both, or neither, depending on the patient's comfort level (see Fig. 190-8). Other considerations include whether the patient lives alone and can adjust a figure-eight; as opposed to a sling, use of a figure-eight also leaves the elbow and hand free for daily activities. If the fracture site produces pressure and tenting of the skin, refer the patient for possible surgery. Because nonunion of middle third (midshaft) factures is rare (<1%), such fractures rarely require referral (usually only for symptomatic nonunion after 12 to 16 weeks). Inner third (proximal) clavicular fractures need be referred only if there is significant displacement or an associated sternoclavicular dislocation. Distal third (lateral) clavicular fractures should be referred if the coracoclavicular ligament is torn and the proximal fragment displaced (type IIB, Fig. 190-5). Because distal third fractures that extend into the acromomioclavicular joint can lead to future degenerative changes in that joint, some primary care clinicians also refer these fractures (type III, see Fig. 190-5). Otherwise, symptomatic therapy is indicated for most clavicular fractures.

Clavicular fractures require a minimum of 2 months for solid union, and contact sports should be avoided for 8 to 10 weeks. (Do not be dismayed if the 1-month follow-up x-ray shows no sign of

**Figure 190-5** Clavicle fractures. **A,** Fractures of the clavicle are classified by location into the distal (15%), middle (80%), and inner (proximal) (5%) thirds. Clavicle fractures can be nondisplaced, displaced, angulated, or nonangulated. **B,** Classification of fractures of the distal third of the clavicle (Allman). Type I: minimal displacement with ligaments intact. Type IIA: proximal shaft is displaced with ligaments intact. Type IIB: clavicle displaced coraccolavicular ligament ruptured but trapezoid ligament intact. Type III: fracture of the articular surface with no disruption of the ligaments.

healing! In fact, this x-ray can be omitted if there are no new symptoms.) Patients should be seen every 2 to 3 weeks; radiographs are indicated only after clinical union (nontender locally and with full range of motion) has occurred or for late development of symptoms. Remember to adjust the figure-eight splint to ensure that it is tight enough to be supportive and keep the shoulders back ("position of attention"), yet loose enough to avoid tingling and numbness from

pressure on the brachial plexus where the splint wraps around the armpit. Instruct the patient to loosen or tighten the brace for more support, if needed, or to reduce restriction if tingling and numbness occur. It should be worn until there is no more tenderness or crepitus at the fracture site.

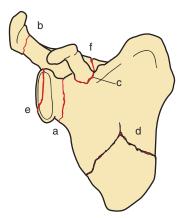

For clavicular fractures, always listen to the chest to exclude a pneumothorax, especially for fractures due to motor vehicle accidents. A chest x-ray is also appropriate. Instruct the patient to report any shortness of breath immediately.

# **Scapular Fractures**

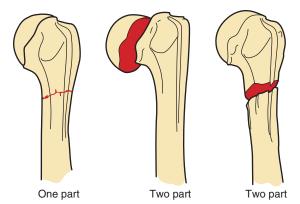

The scapula is covered on all sides with muscle and has an excellent blood supply; therefore, fractures of the scapula (Fig. 190-6) heal extremely well, even when displaced. Most fractures of the scapula need only a sling or shoulder immobilizer for comfort for 2 weeks. Even these measures may not be needed for fractures of the scapular spine, body, or coracoid. For suspected scapular fractures, always obtain a true AP of the glenohumeral (shoulder) joint, an axillary view, and a true lateral scapular Y view. These views will help exclude any intra-articular extension into the glenoid shoulder socket. (A cephalic tilt view can help evaluate the coracoid process.) If any questions remain about a fracture being intra-articular or displaced at the glenoid, a CT scan should be obtained. Significantly displaced coracoid fractures, especially if combined with a complete acromioclavicular separation, displaced acromion fractures, displaced glenoid neck fractures associated with a clavicular fracture, and glenoid fractures involving more than 25% of the articular surface (or those with an associated subluxed humeral head) should be referred. For all others, early range of motion activities should be encouraged, as tolerated. Patients should be seen every 2 to 4 weeks to ensure adequate progress in their rehabilitation program. Evidence of radiographic healing should be present before resistance exercises are initiated.

#### **Proximal Humerus Fractures**

After obtaining true AP and lateral scapular Y or axillary views, fractures of the proximal humerus can be classified by the Neer system (Fig. 190-7) and are considered a one-part fracture if they are displaced less than 1 cm or angulated less than 45 degrees. Patients with fractures displaced more than 1 cm (the minority of fractures) or associated with joint instability or a dislocation should generally be referred. Fractures involving the bicipital groove may interfere with function and therefore also probably warrant referral. Angulation up to 45 degrees is tolerated amazingly well by most individuals, so referral is necessary only for greater angulation; however, athletic or very active individuals may warrant consulta-

**Figure 190-6** Scapular fractures (anterior view): neck (a); acromion process (b); coracoid process (c); body (d); glenoid rim or articular cartilage (e); spinous process (f), which is posterior and only partially seen here.

**Figure 190-7** Neer classification of proximal humerus fractures. One-part or minimally displaced fracture is defined as no segments displaced more than 1.0 cm or angulated more than 45 degrees. A two-part fracture is defined as one segment displaced more than 1.0 cm or angulated more than 45 degrees.

tion when angulation approaches 20 degrees. Most fractures in older patients are immediately below the tubercles, in the area of the surgical neck, which generally has a good blood supply (as opposed to the anatomic neck, immediately beneath the humeral head). As long as there is at least 50% overlap of fracture segments on the AP and scapular Y views, treatment with a shoulder immobilizer for 2 weeks is appropriate, followed by gentle passive and active assistive range of motion exercises to minimize stiffness (Fig. 190-8). The shoulder immobilizer is worn 24 hours a day, except when performing physical therapy or exercise. The shoulder immobilizer prevents displacement of the fracture at night while sleeping. Remind the patient not to use the arm for heavy activity during the day. Protection of the shoulder for these fractures is appropriate for a total of 6 weeks before returning to regular activities.

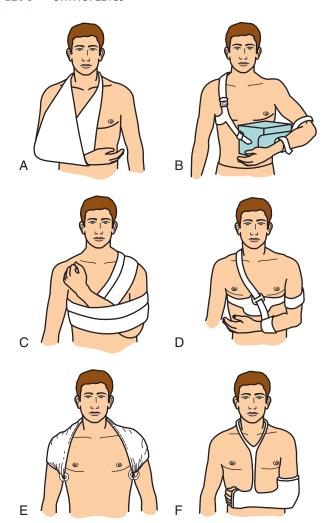

In all fractures, palpation for resolution of point tenderness at the fracture site is a very reliable clinical index of solid fracture union. This finding combined with radiographic union determines when patients can return to full activity without restriction.

#### **Humeral Shaft Fractures**

Humeral shaft fractures are unique in the amount of angulation (of a long bone) that can be allowed; they are also unique in their excellent healing rate (low incidence of nonunion) for long bone shaft fractures. These distinctions are due to the excellent blood supply provided, in part, by a large amount of surrounding muscle tissue. This surrounding muscle tissue can also shelter significant angulation with little resultant cosmetic defect.

For these reasons, and because the shoulder and elbow have excellent motion, up to 30 degrees of mediolateral angulation, up to 20 degrees of anteroposterior angulation, and displacement of up to half the width of the humerus are acceptable when treating a humeral shaft fracture. Treatment consists of a hanging arm cast (see Fig. 190-8F) that extends from the humerus, around the elbow flexed at 90 degrees, and down to the wrist. This position is maintained until callus formation is detected and the fracture site is stable to manual stress, which can take from 8 to 14 weeks. Alternatively, if there is radiographic evidence of healing at 1 month and decreased tenderness at the fracture site, the hanging arm cast can be removed and a functional humerus cast brace (Fig. 190-9) applied.

Made from polyethylene, functional humerus cast braces are available "off the shelf" at local brace supply shops. They wrap around the midshaft of the humerus and provide circumferential compression of the muscle belly, resulting in some hydraulic stabilization at the fracture site. The patient may move the shoulder and elbow in the brace and begin using the arm with such light activities as eating, brushing the teeth, and reading a newspaper. When

**Figure 190-8** Possible methods of immobilization of the shoulder. **A,** Simple shoulder sling is used for humerus, clavicle, and radial head fractures. **B,** Abduction pillow shoulder immobilizer is used for rotator cuff tendon tear after surgery. **C,** Sling and swathe bandage is used for severe acromicolavicular separation and fractures of upper humerus. **D,** Shoulder immobilizer is used for humeral neck fractures. **E,** Figure-of-eight strap for fractures of the clavicle. **F,** The hanging arm cast is used for humeral neck and humeral shaft fractures. It provides weight and traction to align the fracture "pieces."

immobilized, even for a short period, the elbow is notorious for becoming stiff with possible permanent limitation of motion. For this reason, any time the elbow is immobilized for treatment of a humeral fracture at the shaft or shoulder, encourage the patient to adjust the brace and allow the elbow to hang straight in full extension for 15 minutes each day.

When managing these fractures, weekly radiographs are recommended for the first 4 to 6 weeks, until it is clear that the fracture fragments are not moving appreciably. At that point, the patient can be seen and radiographs repeated every 2 weeks until a satisfactory functional result is obtained.

At the time of the fracture, patients with neurovascular deficits should be referred emergently; surgical exploration may be necessary. Although radial nerve exploration is not always indicated when radial nerve function is absent or weak (e.g., weakness in finger or wrist extension), many primary care clinicians will refer in this situation. (As it turns out, radial nerve function almost always returns during the 6 months following an injury, but neither the clinician nor the patient may be willing to wait.) If the patient's radial nerve function is initially normal but becomes impaired after

**Figure 190-9** Functional humerus cast or fracture brace. (Courtesy of AliMed, Inc., Dedham, MA.)

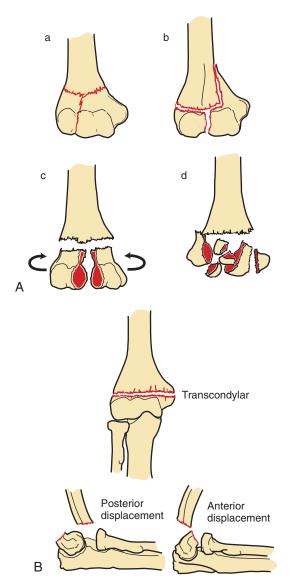

splinting or casting, the splint or cast should be removed, a brace or shoulder immobilizer applied, and the patient referred to an orthopedist for evaluation and treatment. Other indications for referral at the time of the fracture include pathologic fractures, associated elbow injuries, and the presence of multiple injuries.

# Supracondylar and Transcondylar Humeral Fractures

Nondisplaced or minimally displaced (<20 degrees apex anterior angulation on lateral x-ray) supracondylar and transcondylar fractures (Fig. 190-10) can be treated with a posterior long-arm, fiberglass, one-step prepadded splint. The elbow should be held at 90 degrees of flexion, and a shoulder immobilizer (see Fig. 190-8D) used. The distal pulses should be checked after splint application; if absent, the elbow should be extended until they return. True AP and lateral radiographs of the distal humerus should be obtained after immobilization to confirm that no displacement occurred during efforts to immobilize. During the first 7 to 10 days, frequent checks of neurovascular function are necessary. Follow-up radiographs should be reviewed weekly for the first 2 to 3 weeks, and then every 2 weeks until callus formation is seen. When significant tenderness is no longer felt at the fracture site, the splint can be removed to allow gentle range of motion activities (usually at 2 weeks). The patient should be instructed to avoid any passive motion at the elbow because it will predispose the elbow to ectopic bone formation and permanent stiffness. The splint is used for protection until adequate callus forms (usually 6 to 8 weeks), but is removed for showers, bathing, and gentle exercise, usually starting 2 weeks after the injury.

# **Intercondylar Fractures**

Displaced intercondylar fractures (see Fig. 190-10A) are unstable and should be referred to an orthopedic surgeon. Nondisplaced fractures should be managed the same as nondisplaced supracondylar or transcondylar fractures; however, the risk of neurovascular compromise is less, so the patient does not need as many follow-up visits in the first 7 to 10 days.

**Figure 190-10 A,** Intercondylar fractures of the humerus: No displacement of fragments (a); T-shaped fracture with the trochlear and capitellar fragments separated but not appreciably rotated in the frontal plane (b); T-shaped fracture with separation of the fragments and significant rotational deformity (c); T-shaped intercondylar fractures with severe comminution of the articular surface and wide separation of the humeral condyles (d). **B,** Transcondylar fractures of humerus, demonstrating significant posterior (*left*) and anterior (*right*) displacement.

# Fractures of the Humeral Condyles

Type I fractures of the humeral (epi)condyles (Fig. 190-11) are treated with a splint in a manner similar to nondisplaced supracondylar and transcondylar fractures as previously discussed. The joint hemarthrosis should be aspirated and the elbow immobilized in a posterior splint with 90 degrees of flexion. For a medial condyle fracture, the forearm is placed in pronation and the wrist slightly flexed. For a lateral condyle fracture, the forearm is placed in supination and the wrist slightly extended. Radiographs should be obtained every 3 to 5 days for the first 2 weeks, then weekly thereafter to ensure no late displacement of the fragments. Patients with type II fractures of the humeral (epi)condyles should be referred to an orthopedic surgeon.

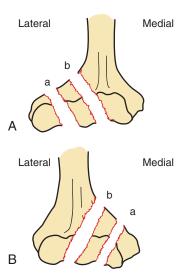

Figure 190-11 Fractures of the humeral (epi)condyles. A, Lateral humeral condyle: Type I, simple fracture of the lateral condyle with lateral wall of trochlea attached to main mass of the humerus (a); type II fracture with lateral wall of trochlea attached to fractured lateral condylar fragment (b). B, Medial humeral condyle: Type I, simple fracture of medial condyle with medial wall of trochlea attached to main mass of the humerus (a); type II fracture with medial wall of trochlea attached to fractured medial condylar fragment (b).

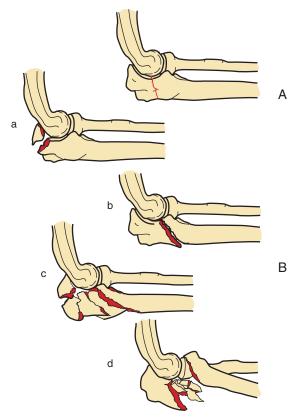

#### **Elbow Fractures**

All displaced (>2 mm) olecranon fractures (Fig. 190-12) should be referred to an orthopedic surgeon. If the patient is unable to actively extend the elbow (i.e., loss of triceps function), an orthopedic surgeon should be consulted. Otherwise, the patient should be immobilized in 60 to 90 degrees of flexion and seen in follow-up in 5 to 7 days. Radiographs should be evaluated in that visit to assure no displacement and at the 2- and 4-week visits. Range of motion activities should be started at 2 weeks with motion limited to 90 degrees of flexion until there is radiographic evidence of fracture healing.

Radial head fractures (Fig. 190-13) displaced more than 2 mm, involving more than a third of the articular surface, angulated more than 30 degrees, depressed more than 3 mm, severely comminuted, or with an associated dislocation should be referred to an orthopedic surgeon. Otherwise, treatment is range of motion activities such as pronation, supination, and elbow flexion and extension, as soon as pain permits, usually within 3 to 5 days. The patient should apply ice intermittently to the joint and keep it elevated for the first 48 hours. Significant pain relief can be provided by aspiration of blood from the joint followed by instillation of a local anesthetic. Immobilization is not required, but if the patient experiences too much pain without immobilization, a long-arm fiberglass one-step 90-degree splint and sling can be used. It should be removed as soon as possible to minimize stiffness. With radial head injuries, always check the wrist to ensure that there is no tenderness over the distal radius or ulna; associated injuries to the wrist often result in instability. If tenderness is present over the wrist, obtain true AP and lateral radiographs. For any displacement or dorsal subluxation of the ulna, with or without a fracture, the patient should be referred to an orthopedic surgeon.

#### **Midforearm Fractures**

An isolated fracture of the ulnar shaft (nightstick fracture) with no fracture or dislocation of the radius can be treated with a long-arm splint and sling with the elbow in 90 degrees of flexion. The splint remains in place for protection for 6 to 8 weeks. Weekly radiographs

**Figure 190-12** Olecranon fractures. **A,** Nondisplaced. **B,** Displaced fractures: Avulsion fracture (a); oblique and transverse fracture (b); comminuted fractures (c); fracture dislocations (d).

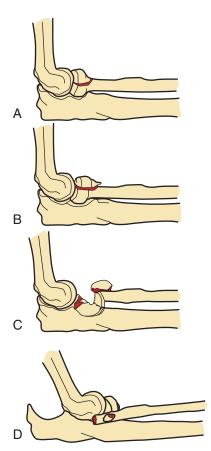

should be obtained for the first 3 weeks to detect any displacement and then at 6 to 8 weeks to document union. The fracture of the ulna will become sticky, stable, and less painful after 3 weeks, allowing removal of the splint for gentle range of motion activities of the elbow, including pronation and supination of the forearm twice a day for 15 minutes to minimize stiffness. Alternatively, a functional forearm brace can be applied after the intial swelling goes down in 7 to 10 days and remain in place until union is documented radiographically.

A fracture of the radial shaft (Galeazzi's fracture) requires surgery in all cases, so these patients should be referred to an orthopedic surgeon. Even if nondisplaced initially, the fracture will often become displaced, and the distal radioulnar joint is usually affected. Patients with both-bone shaft fractures (radial and ulnar shafts) should usually be referred to an orthopedic surgeon because these fractures usually require open reduction and internal fixation as a result of instability.

# **Distal Forearm Fractures**

# Colles' Fracture

A Colles' fracture involves the distal 2 cm of the radius, is angled dorsally (Fig. 190-14), and is the most common wrist fracture. If extra-articular and nondisplaced, it can be treated with a double sugar-tong splint (one splint from elbow to wrist, the other over initial splint and extending from elbow to axilla) for 3 to 5 days followed by a short-arm cast for 4 to 6 weeks. The fracture should be followed with radiographs at 1 (splint removed), 2, and 6 weeks to ensure no displacement and complete healing. At 6 weeks, the radiograph is taken after cast removal to assess fracture healing; if tenderness persists at the fracture site or there is incomplete union,

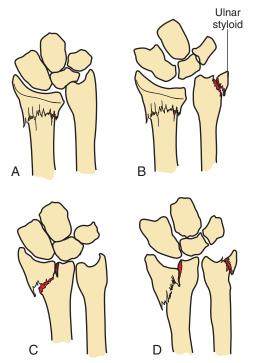

**Figure 190-13** Radial head fractures (Mason classification with Johnston modification). **A,** Nondisplaced linear or transverse fractures. **B,** Fractures with minimal displacement (or comminuted fractures without displacement [not shown]). **C,** Comminuted fractures with marked displacement. **D,** Radial head fracture with associated elbow dislocation.

an ulnar gutter splint should be applied. This splint can be removed to allow gentle range of motion activities, but should then be reapplied each time until all tenderness resolves and a solid fracture union is noted on the radiograph.

Colles' fractures require reduction if the lateral x-ray shows the distal radius articular surface to be tilted dorsally beyond the neutral position (determined by a line drawn straight through the distal radius, lunate, and capitate). After reduction, the distal articular surface should be perpendicular to the long axis of the forearm (neutral) or tilted volarly. If not reducible, unstable, comminuted, or intra-articular, these fractures are best treated by an orthopedic surgeon. Colles' fractures in the dominant wrist of the "high demand" (i.e., very active) patient are also more likely to require surgery for a satisfactory result.

On the AP view, if the radius is not equal to or longer than the length of the ulna, reduction is also indicated. Most patients have a radius that is longer than the ulna; this characteristic is referred to as negative ulnar variance as seen on the AP radiograph. (In a few patients, the radius and ulna are the same length; if any doubt remains, a comparison AP radiograph can be assessed). If there is displacement at the fracture site as defined by shortening of the radius on the AP view, reduction is indicated.

Reduction is simplified by injecting 10 mL of plain 1% lidocaine into the fracture site hematoma (hematoma block) for anesthesia. This injection should be performed slowly to minimize any pain associated with distention. The skin surface can be iced or sprayed with ethyl chloride to decrease the discomfort associated with the injection. Always clean the skin after applying the spray with an antiseptic preparation (e.g., povidone–iodine, chlorhexidine,

**Figure 190-14** Distal radius fractures. **A,** Colles' fracture. **B,** Colles' fracture is commonly associated with fracture of ulnar styloid. **C,** Intra-articular fracture. **D,** Intra-articular fracture of radius with associated fracture of ulnar styloid.

alcohol) before injecting lidocaine. The patient should be supine during the entire procedure including the injection.

After the hematoma block has had time to take effect (10 minutes), hang the patient's hand in finger traps traction with the elbow flexed 90 degrees, and gradually add counterweights to a weight hanger, orthopedic felt sling, or stockinette draped over the humerus (Fig. 190-15). A weight of 5 to 10 lb is appropriate, and the patient should be in this suspended traction position for 15 to 20 minutes. At that point, reduction is usually achieved spontaneously by ligamentotaxis (the soft tissue attachments to the bone pull the bone into a reduced position in response to the traction). If any visible or palpable deformity remains after 15 to 20 minutes of traction, manual pressure can then be used to correct the deformity. Push from dorsal to volar over the distal radius, distal to the fracture site. Following reduction, with the arm still maintained in traction, as mentioned previously, the double sugar-tong splint should be applied. After 3 to 5 days, a long-arm, well-molded cast is applied (it is started as a short-arm cast and extended). Take great care to mold with your thenar cone at the base of the thumb, pressing into the patient's palm to prevent a gap in the volar portion of the cast

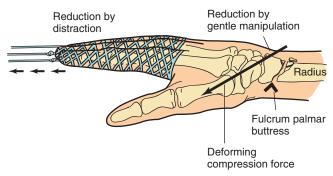

Figure 190-15 Treatment of Colles' fracture to effect reduction.

at the palm. After the cast is hard, trim it back to the proximal palmar crease to allow full flexion of the metacarpophalangeal (MP) joints to prevent joint stiffness.

After the cast is hard and three-point molding is applied (pushing volarly distal to the fracture site, dorsally just proximal to the fracture site, and volarly against the elbow), the cast is extended to the long-arm level, which is at least 5 inches more proximal, above the elbow. Be careful to pad the cast margins well, proximally and distally, and to stop application of plaster or fiberglass at least 1 inch before reaching the padding margin.

True AP and lateral postreduction radiographs should then be obtained. If the dorsal tilt of the distal radius articular surface or shortening of the radius in relation to the ulna persists, then the reduction is unacceptable and referral should be made for repeat reduction under general anesthetic and the possible application of skeletal external frame traction.

Ulnar styloid fractures indicate a larger force of injury and a higher chance of eventual loss of reduction. However, surgical treatment is never required for an isolated displaced ulnar styloid fracture. These fractures often remain nonunited on follow-up radiographs, but this has no clinical significance. Although patients may look at the radiograph and think they have a loose piece of bone floating around the wrist, they should be reminded that this bone is attached to soft tissue, does not float freely, and will not move.

#### Smith's Fracture

A *Smith's fracture* is similar to a Colles' fracture except that the angulation is volar (so it is sometimes called a reverse Colles'). After reduction, this fracture is treated the same as a Colles' fracture, with a double sugar-tong splint followed by a long-arm cast. If the fracture is intra-articular or the reduction is not anatomically correct, refer the patient to an orthopedic surgeon. This is an uncommon fracture and is often unstable; most should be referred.

# Fractures of the Carpal Bones

Most chip and avulsion fractures of the carpal bones are treated with a gutter splint for comfort and protection for 4 to 6 weeks until symptoms resolve. The gutter splint can be removed for a shower. Hook of the hamate fractures should be referred to an orthopedist.

# Scaphoid (Navicular) Fractures

When there is pain in the "snuffbox," always consider a scaphoid (navicular) injury (Fig. 190-16). Lateral, posteroanterior (PA), and motion (flexion-extension, radial deviation-ulnar deviation) views may be helpful. If a fracture is seen, a scaphoid magnification view

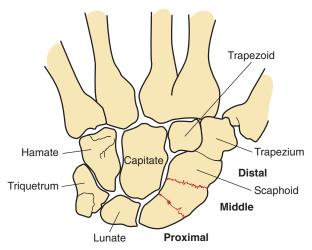

Figure 190-16 Scaphoid (navicular) fractures.

radiograph and consultation with a radiologist or orthopedist may help confirm that the fracture is, in fact, nondisplaced. A limited CT or MRI scan may also be helpful. Because the best blood supply (and highest likelihood of healing) is distal, nondisplaced distal third fractures (see Fig. 190-16) can be treated with a short-arm thumb spica cast for 4 to 6 weeks. Middle or proximal third fractures (see Fig. 190-16) need a longer cast and treatment; a long-arm thumb spica cast is applied for 6 weeks, followed by a short-arm thumb spica cast for another 6 weeks. Some clinicians continue the short-arm thumb spica cast for up to 14 more weeks for proximal third fractures.

A short-arm thumb spica cast is appropriate for any patient who has significant tenderness over the snuffbox (scaphoid), with follow-up radiograph and examination in 2 to 3 weeks without the cast. If at that time no tenderness is felt over the scaphoid and no fracture is visible, then there was no scaphoid fracture. Scaphoid fractures are notorious for being difficult to diagnose radiographically in the acute setting. For this reason, always err on the side of immobilization when a scaphoid fracture is suspected. If after 2 to 3 weeks the cast is removed and no fracture line is visible but persistent tenderness is noted over the fracture site, immobilization for an additional 2 to 3 weeks is appropriate, followed by repeat radiographs. At that point, if no fracture line is visible, then there was no scaphoid fracture and gentle range of motion exercises can be initiated. A bone scan may also help confirm a fracture.

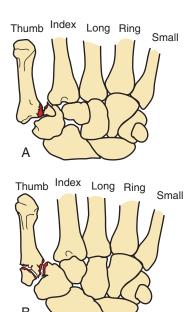

Displaced scaphoid fractures should be referred to an orthopedic surgeon. Avascular necrosis, delayed union, nonunion, and arthritis are common complications of scaphoid fractures, even if managed appropriately; therefore, the patient needs to be made aware of these risks at the start.

# **Metacarpal Fractures**

Nondisplaced, noncomminuted metacarpal fractures, including those that are intra-articular (except thumb metacarpal), are treated with an ulnar or a radial gutter cast, depending on the fracture location. Nondisplaced, noncomminuted, nonarticular fractures of the thumb (first) metacarpal are treated with a thumb spica cast. An index (second) finger metacarpal fracture can be treated with a radial gutter cast with a hole cut out for the thumb to allow thumb function. Fractures of the middle (third), ring (fourth), and little (fifth) finger metacarpals are treated with an ulnar gutter splint. A gutter splint can be made using 6-inch wide one-step fiberglass prepadded splint material. Patients should be seen every 2 weeks.

Nondisplaced fractures of the metacarpal heads can be treated with a gutter splint for 2 to 3 weeks. Nondisplaced fractures of the second or third or mildly angulated fractures of the fourth (<30 degrees) or fifth metacarpal (<40 degrees) neck can be treated in the same manner for 3 to 4 weeks so long as there is no rotational deformity. If the fracture is in the midportion of the shaft, and there is no rotational deformity, mildly angulated second or third metacarpal (<10 degrees) or fourth or fifth metacarpal (<20 degrees) fractures can be managed with gutter splinting for 3 to 4 weeks. For angulation greater than these parameters, reduction can be attempted. If reduction is unsuccessful, or if there is a rotational deformity, the patient should be referred. Hematoma block reduction can be carried out with three-point pressure fixation in the splint, followed by postreduction radiographs. After 3 to 4 weeks, the gutter splint can be removed for range of motion exercises. When not performing range of motion movements, the metacarpal should remain protected in the splint for an additional 3 weeks.

Immobilize the metacarpals with 90-degree flexion at the MP joint and full extension of the interphalangeal (IP) and distal interphalangeal (DIP) joints of the fingers. Often referred to as the "intrinsic plus position," this position results in the MP joint lateral ligaments and those of the DIP and proximal interphalangeal (PIP) joints being in maximal stretch. This position prevents tightening during immobilization and secondary stiffness of the joint. The

**Figure 190-17** Displaced intra-articular fractures of the proximal thumb. **A,** Bennett fracture. **B,** Rolando fracture.

gutter cast should go from the tips of the fingers to the midforearm. Remember to place dry cotton ball padding between the fingers to prevent skin maceration from moisture accumulation.

Immobilizing all metacarpal fractures in an MP joint flexion 90-degree position minimizes the risk for future malrotation; the flexed finger at the MP joint serves to align the metacarpal in the correct direction with the adjacent metacarpals. This alignment acts as a reference angle because the protective fingers are also flexed 90 degrees.

Patients with displaced intra-articular fractures (Bennett and Rolando fractures) should be referred to an orthopedic surgeon, especially those who have intra-articular fractures at the base of the thumb (Fig. 190-17). Even nondisplaced intra-articular fractures of the base of the thumb should probably be referred. Nondisplaced fractures of the thumb shaft with more than 30 degrees of angulation should be reduced under a Bier or hematoma block and managed with a thumb spica cast for 4 weeks.

Boxer fractures occur at the fifth metacarpal neck. As mentioned previously, angulation up to 40 degrees is acceptable for this fracture. The clinician must be certain, however, not to confuse a boxer fracture (fifth metacarpal neck) with a fifth metacarpal shaft fracture (Fig. 190-18), because angulation of the shaft of the fifth metacarpal greater than 20 degrees is unacceptable. If the reduction is lost somewhat during healing of a fifth metacarpal neck, it will mainly

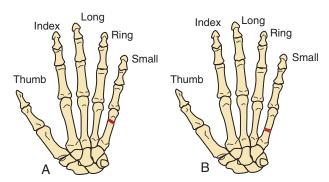

Figure 190-18 A, Boxer fracture. B, Metacarpal shaft fracture.

result in a cosmetic, as opposed to a functional, deformity. Also, explain to patients that with boxer fractures the bone will heal with abundant callus; consequently, they will have a bump over the dorsum of the hand because the callus is subcutaneous.

When treating boxer fractures, be cautious of any mark on the skin over the knuckle, which could suggest an open fracture or a human bite lesion that might become infected. If either is present, begin broad-spectrum antibiotics, possibly giving the first dose intravenously. The wound should be inspected again in 2 to 3 days to ensure no infection.

An isolated fracture involving one of the long or ring finger metacarpals can be treated without immobilization if the patient is comfortable and wishes to use the hand out of a cast. Approximately 3 to 5 mm of shortening of the finger may occur as the metacarpal overrides itself. However, no shortening will occur beyond this point because the fractured metacarpal is being suspended between the two intact metacarpals and associated interosseous ligaments that run between the metacarpals.

# **Phalangeal Fractures**

Phalangeal fractures can be immobilized with aluminum foam splints, buddy taping, or stack splints (e.g., mallet finger fracture of distal phalanx). If there is any displacement of these fractures, closed reduction is unsuccessful, or reduction cannot be maintained, referral is appropriate. Volar plate avulsion fractures caused by hyperextension injuries at the PIP joint are best immobilized with a dorsal block splint holding the PIP joint in 45 degrees of flexion for 3 weeks.

Transverse or angulated fractures of the distal phalanx are often unstable and difficult to reduce because of interposition of soft tissue. Intra-articular fractures of one or more condyles of the middle or proximal phalanx at the level of the DIP or PIP joints, respectively, usually also need referral for internal fixation. Oblique or spiral proximal shaft fractures and large displaced avulsion fractures of the base of the proximal phalanx may also benefit from referral for operative repair. Conversely, mallet finger fractures should be treated with continuous slight hyperextension splinting for up to 8 weeks. Almost all other finger fractures can be treated with 3 or 4 weeks of buddy taping.

Always check the collateral ligaments by stress examination. Use a digital block if needed to perform the examination. If collateral ligaments are disrupted despite a negative x-ray, buddy taping is appropriate for protection for 1 month while allowing protected range of motion movement in the taped position.

In general, with metacarpal and phalangeal fractures, *malrotation* is the most common complication. To exclude malrotation with a metacarpal fracture, always hold the MP joints in 90 degrees of flexion to ensure perfect rotational alignment. For phalangeal fractures, always note the plane of the nail beds while looking at the fingers from the ends. Compare them with the opposite hand to ensure correct rotational alignment.

Any intra-articular fracture with displacement at the joint surface should be referred to an orthopedic surgeon for reduction and fixation. Proximal interphalangeal joint fractures involving more than 40% of joint surface should be referred for probable internal fixation. Extra-articular and intra-articular fractures without displacement at the joint surface can be treated without referral. If any doubt remains as to whether displacement in the joint surface is present, consult a radiologist or orthopedist.

## **CHILDREN'S FRACTURES**

Children's bone tissue is elastic, similar to a plastic flyswatter handle. For this reason, their bones can deform and bow without cracking the cortex. This elastic deformation commonly occurs in the shaft of the radius or ulna and is referred to as a bone bow fracture. If concerned about the alignment of the forearm, remember that the

ulna is always straight and that a small 10- to 20-degree bow is normally present in the radius. Assessment of a *comparison film* can determine what is normal for the patient. When viewing comparison films, always make sure the views are taken in exactly the same projection so that a true comparison can be made. Comparison films in children are also beneficial because the growth plates ossify at different ages.

Comparison radiographs in children are especially important when treating any elbow injury, because numerous ossification centers develop at various ages (from 3 to 12 years). Because of these various centers of ossification, if any sign or question of fracture is present, a radiologist should be consulted or referral to an orthopedist considered to review the films. *Salter's classification* is commonly used for children's fractures involving the growth plate (Box 190-2 and Fig. 190-19).

#### Box 190-2. Salter's Classification of Fractures\*

Salter type I fracture is diagnosed with a normal x-ray appearance and by point tenderness directly over the growth plate. No tenderness should be felt over the ligaments around the joint. This type of fracture is common in infants and young children. Treatment is always closed with cast immobilization.

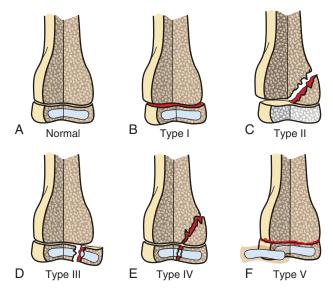

Salter type II is a fracture through the growth plate and then through the metaphysis. This type of fracture is more common in older children. The prognosis for growth disturbance is very high when the fracture involves the distal femoral growth plate. Refer all patients with this type of fracture to an orthopedic surgeon if any displacement has occurred. Reduction is almost always performed with a general anesthetic to provide complete muscle relaxation. This relaxation allows the traction to decrease the force across the growth plate, which is required to set it. The less force required to set the fracture, the less recurrent injury to the growth plate itself (see Fig. 190-19).

Salter type III fracture involves the epiphysis extending into the epiphysial plate. If any displacement has occurred, the patient should be referred to an orthopedic surgeon. These fractures are most common in the distal tibia and can be associated with growth arrest. Anatomic reduction is always required, and surgery may be required.

Salter type IV fracture extends from the joint surface through the epiphysis and on through the epiphysial plate and out through the metaphysis. These fractures are often displaced and require open surgical treatment. This fracture most commonly occurs at the lateral humeral condyle at the elbow. These injuries extend into the joint. If the fracture appears nondisplaced and any question of displacement remains, it may be beneficial for a radiologist or an orthopedist to review the film and tomograms.

Salter type V injury is a crush injury of the epiphysial plate and is uncommon. When this fracture occurs, it is usually at the knee or ankle and associated with growth arrest. The x-ray appearance may be normal as for a Salter type I fracture. For this reason, parents (and the child) should be cautioned that growth arrest can occur if there is tenderness over the growth plate, whether it is a Salter I or Salter V fracture (and often this is difficult to determine) because it may have extended into the growth plate. Osteoarthritis can occur as a result of any fracture that extends into the joint itself, whether this occurs in an adult or a child.

<sup>\*</sup>See Figure 190-19.

**Figure 190-19** Illustrations of Salter's classification for fractures in children (also see Box 190-2). **A,** Normal. **B,** Type I. **C,** Type II. **D,** Type III. **E,** Type IV. **F,** Type V.

It is appropriate to refer all fractures in children involving the spine or knee because fractures around the spine and knee are at high risk for growth plate arrest or neurologic injury.

# **Upper Extremity Fractures**

Clavicle fractures do not generally require referral, reduction, or intervention unless tenting of the skin is observed with whiteness over the skin as a result of loss of blood supply. Exceptions include a clavicular fracture near the acromioclavicular joint that is displaced or in the proximal third of the clavicle displaced posteriorly; these should be referred to an orthopedic surgeon. The vast majority of fractures, however, occur in the middle third of the clavicle or are nondisplaced and are treated with a figure-eight strap for immobilization and comfort. Remember, the figure-eight strap is applied only to increase comfort; children heal very rapidly (within weeks), and as soon as the child is comfortable without it, the strap is no longer required. In toddlers, a figure-eight strap is unnecessary because healing occurs so quickly. In older children, a sling may be more comfortable than a figure-eight strap. These straps and splints can be removed for bathing and then reapplied. To show patients how to put the straps back on and get the straps in the same position, instruct them to use a pen to make marks on the white straps at the level of the buckles. This "trick" will enable the patient to reapply the splint, sling, or brace in the same position with the same degree of tension as applied in the office.

Rib fractures, similar to those in adults, do not require treatment, immobilization, or bracing. Although patients may ask for any one of these treatments, remind them that splints or rib binders can cause atelectasis or pneumonia. Always auscultate the chest to exclude pneumothorax and respiratory compromise. Sometimes subcutaneous emphysema suggests lung puncture by a rib or clavicular fracture. This complication can be ruled out by palpating the skin around the area of the fracture to check for any crepitance.

Fractures around the shoulder usually involve only the surgical neck of the humerus. As long as there is 50% bone-on-bone contact and not too much angulation (<70 degrees before age 5, <40 degrees from age 5 to 16, <25 degrees after age 16), no reduction is necessary. As with adults, treatment is a hanging arm cast for 3 to 4 weeks until tenderness resolves on palpation and comfort is present. Humeral shaft fractures almost always heal well, and angulation up

to 25 degrees on AP and lateral planes can be accepted. Always check for radial nerve dysfunction.

Distal humerus supracondylar fractures are best evaluated with comparison of true lateral radiographs. Remember that the distal humerus ordinarily has a tilt in an anterior direction. If the distal humerus is entirely straight, approximately 10 to 15 degrees of bending of the distal humerus has occurred in a posterior direction. This bending is acceptable, however, as long as the humerus is not bent backward beyond the straight position. As it turns out, most supracondylar fractures in children are displaced and require referral. Nondisplaced fractures with good alignment can be treated with a long-arm cast for 3 weeks with the elbow at 90 degrees and the forearm in neutral rotation.

A supracondylar fracture or radial head or neck fracture can be identified with a posterior fat pad sign. The posterior fat pad sign is the result of intra-articular bleeding in the elbow joint with any fracture that is intra-articular. The blood goes into the olecranon fossa in the distal humerus and causes the fat pad that resides there to float posteriorly; therefore, it is no longer hidden in the olecranon fossa. As it floats posteriorly, it is visible as a fat pad on the true lateral radiograph of the distal humerus. In the absence of any abnormality on the radiograph, a fat pad sign indicates bleeding into the joint and leads to a diagnosis of occult fracture most likely involving the radial head or neck. This involvement can be confirmed by point tenderness with palpation of the radial head and neck. Angulation up to 30 degrees and up to 4 mm translocation are acceptable in fractures of the radial head or neck; a child with greater angulation or translocation should be referred to an orthopedic surgeon for probable closed reduction.

Common fractures in the forearm include *torus fractures*. They are treated with a short-arm cast for 1 month until all tenderness resolves. *Greenstick fractures* are one level worse than torus fractures; these involve an actual crack or disruption of one cortex and often a buckling of the opposite cortex. These fractures are so named because they represent a deformation of the bone much like cracking a green twig on an apple tree in springtime. The tension side of the bent twig cracks, whereas the compression side (concave side) buckles and does not crack.

Any angulation in the radius greater than 10 degrees in children older than 8 (or >15 degrees in children younger than 8) requires reduction and should be referred. Significantly comminuted fractures or those associated with nerve injury should also be referred. With ulnar shaft fractures, angulation greater than 15 degrees should be reduced; if uncomfortable performing this reduction, the primary care clinician should refer the patient. For all other radial or ulnar shaft fractures (including both-bone fractures if non-displaced or minimally displaced), a long-arm cast can be utilized for 6 to 8 weeks to prevent pronation and supination at the elbow. The cast is always applied with the elbow in at least 90 degrees of flexion, and the sling must always hold the arm in at least 90 degrees of flexion. If it does not do so or if the cast is applied in less than 90 degrees of flexion, the cast will continue to slip out of the sling.

#### **Wrist and Hand Fractures**

Fractures of the carpal bones are uncommon in children. Management of scaphoid fractures is very similar to that in adults. However, with a fall on the outstretched arm, the typical fracture is of the distal radius and ulna. These fractures can be reduced by hematoma block and finger traps traction, as in the adult. This technique should be reserved for the child who is 12 years or older and very cooperative and understanding. Younger children, who are uncooperative, anxious, or otherwise frightened of injections, should have a reduction under general anesthesia. This approach will provide a more comfortable, less frightening experience and allow maximum muscle relaxation for the least traumatic reduction potentially affecting later arm growth and length.

Metacarpal and phalangeal fractures that are nondisplaced are simply treated with ulnar or radial gutter splint immobilization. The position of immobilization and the angulation are the same as that used for treating adults. Remember, the fifth metacarpal neck can accept angulation up to 40 degrees, whereas the shaft angulation can be accepted only to 20 degrees. Phalangeal fractures, including mallet fingers, are treated the same for children and for adults.

The so-called *octave fracture* is common in children and occurs at the base of the proximal phalanx of the little finger (fifth digit), where it is angulated ulnarly. It is so named since playing the piano requires children to stretch their fingers into wide abduction. Reduction is required and is easily done using a finger digital block anesthetic, followed by placement of a pen or pencil between the fourth and fifth fingers. The pen acts as a fulcrum between the two fingers. The little finger is then pulled back into place with traction and radial deviation until it is perfectly straight using the pen or pencil deep against the web space as a bolster or fulcrum. This technique works extremely well, and should be followed by buddy taping and splint immobilization for a minimum of 3 weeks.

Again, a child with any displaced intra-articular fracture or displaced growth plate fracture should be referred to an orthopedic surgeon for reduction.

# **Lower Extremity Fractures**

Fractures of the true pelvis are uncommon, except in automobile accidents or high-velocity trauma. Patients with these fractures should all be referred to rule out other associated injuries to the abdomen, genitourinary, and gynecologic systems. Apophyseal avulsion fractures are fairly common in young athletes. Those of the anterior inferior or superior iliac spine are usually minimally displaced; hamstring attachment avulsion fractures may result in a large displaced fragment. Conservative treatment consists of a brief period of rest followed by 2 to 3 weeks of crutch-assisted ambulation. Return to full function may take 6 to 12 weeks. Surgery is reserved for those with symptomatic nonunion.

Femur fractures are also uncommon and should be immediately referred to an orthopedic surgeon for further evaluation and treatment. Remember, a slipped capital femoral epiphysis or avascular necrosis of the femoral head in children (Perthes disease) can present with knee pain. The knee examination and radiograph may be entirely normal. The first clue to the diagnosis is limitation of hip internal rotation on the involved side. The Trendelenburg test often shows weakness in the gluteus medius on the involved side. If a child under 17 years of age complains of knee pain and the knee examination and radiographs are negative, always examine and carry out radiographs of the pelvis and hips. AP pelvic and true lateral radiographs of the hips are appropriate studies for this purpose.

Fractures of the distal femur that are nondisplaced and have normal radiographs are diagnosed by point tenderness over the distal femoral epiphysis, which is located 3 cm above the joint line. Treatment involves a cylinder cast for complete immobilization, crutches, and protective partial weight-bearing activities for 1 month. During the follow-up examination, a window can be placed in the cast through which the examiner's finger can palpate for tenderness. As long as tenderness is felt at the fracture site, the cast should remain in place. The tenderness should resolve within 8 weeks or sooner, depending on the child's age.

Patellar fractures are usually nondisplaced and are similarly treated with a knee immobilizer or cylinder cast. Immobilize the knee for 1 month until all tenderness resolves.

Beware of any intra-articular avulsion fractures along the lateral tibial plateau. This type of fracture indicates an anterior cruciate ligament avulsing a piece of bone. If there is any associated displacement, referral to an orthopedist should be carried out for surgical repair.

Proximal tibial fractures are treated the same as those of the distal femur and are diagnosed by point tenderness over the growth plate. Tibial shaft fractures can be treated in a long-leg cast without

reduction if there is not more than 5 degrees angulation on the AP radiograph and not more than 10 degrees angulation on the lateral radiograph. If angulation exceeds these thresholds, referral to an orthopedic surgeon should be made for closed manipulation reduction.

Fibular fractures are of no concern and will heal uneventfully without treatment. However, if any angulation is present, an orthopedic surgeon should be consulted for probable closed manipulation reduction.

#### Foot and Ankle Fractures

Patients with any fracture around the ankle that is displaced should be referred to an orthopedist. Most fractures of the ankle should be managed by an orthopedist because most involve the growth plate. That said, fractures that are nondisplaced can be treated with a short-leg cast and no weight-bearing activity for 2 weeks, followed by advancing to weight-bearing activities for the remaining 3 to 4 weeks while in the cast.

Fracture of the talus, navicular, and cuneiform bones can be treated with a short-leg walking cast, provided there is no displacement. Fractures of the metatarsals are treated the same in children as for adults. Peroneus brevis avulsion fractures can be treated with a wooden-soled fracture shoe. Beware of the fracture of the proximal shaft of the fifth metatarsal (Jones fracture), which is different from a peroneus brevis avulsion fracture. For optimal healing, this type of fracture requires a short-leg fiberglass cast and no weight-bearing activities for 2 weeks, followed by weight-bearing activities for an additional 6 weeks.

#### Child Abuse

Any history or examination suspicious for child abuse should be assessed with long bone radiographs of the upper and lower extremities. This long bone study should be carefully reviewed for signs of fractures in various bones in different stages of healing, which would indicate a history of numerous injuries. A corner fracture is a typical radiographic finding, which is noted at the corner of the metaphysis of a long bone.

# COMPLICATIONS (ADULT AND PEDIATRIC)

Compartment syndrome (see Chapter 188, Compartment Syndrome Evaluation) is the most devastating complication in fracture treatment and is caused by swelling and a tight cast leading to neurovascular compromise. This syndrome most frequently occurs in the calf and forearm. Any patient who requires more than the average dose of oral pain medication for fractures of the forearm or tibia (or any other fracture, for that matter) should be evaluated emergently. If the patient feels the cast is too tight or if there is excess pain beyond what would be reasonably expected, or if any swelling in the digits occurs, then the cast and padding should be immediately split (bivalved). If pain relief does not occur, the entire cast should be removed and the extremity inspected for signs of tenseness of the skin. If the skin is not tense and the calf is involved, perform a Doppler study to rule out phlebitis. Treatment of the fracture and maintenance of reduction of the fracture are always a second priority to preserving the blood supply to the soft tissue and bone. If any question of compartment syndrome remains, compartmental pressure measurements must be obtained and a fasciotomy performed if pressures are elevated.

The higher the velocity of the injury, the more comminuted the fracture, the higher the energy of the force, the more soft tissue trauma, the higher the chance of swelling. For the upper extremity, always tell patients to carry the arm over the head in a "monkey-like" position for the first week. Children may go to school, but their arm should be propped up over the head or on a stack of books in

front of them on their desk. At night, they should sleep with couch cushions elevating the arm. Parents should set their alarm clock for 3 AM and reposition the child's arm back up on the pillows because the child will have most likely wiggled the arm off the elevated position. Be certain that patients *do not* have slings to use for a long-arm cast for the first week. If they are given a sling, they will automatically carry the cast and arm down in front by their chest and it will be lower than the heart and promote swelling. The sling should not be used until after the first week.

Most open fractures should be referred to an orthopedist due to the increased risk of infection. The open fracture may be associated with only a small puncture wound in the skin, and this puncture may be located several inches from the fracture itself because of the forces of deformation at the time of the injury. Fractures of nail beds may become open fractures when the nail is removed; however, primary care clinicians can often repair these (see Chapter 27, Nail Bed Repair).

It is now known that reflex sympathetic dystrophy involves, in fact, a shutdown of the capillary circulation system and results in arterial blood being shunted in a bypass fashion from arterioles to venules without adequate capillary profusion. This phenomenon has been demonstrated by sampling the oxygen content of venous blood in the involved extremity compared with the uninvolved extremity. The oxygen content in the venous blood in an extremity with reflex sympathetic dystrophy is higher, which is due to the oxygen not being taken out by the tissues, as it would be if the blood were supplied normally to the capillary system.

The incidence of *postfracture stiffness* in a joint (especially at the elbow or where the fracture extends into the joint) is dramatically increased in patients who have diabetes and in those who smoke. Patients should understand that diabetes and smoking have similar effects on the capillary blood flow; they both diminish the flow.

Delayed union, nonunion, atrophic or hypertrophic union, and malunion are possible complications of fractures. Inadequate assessment of the initial radiographs, improper management of the fracture (including incomplete reduction), poor patient adherence and compliance, increased age, medications, and presence of osteopenia or osteoporosis are all possible causes of these complications. Smoking or taking anti-inflammatory medications delays the healing time and increases the risk for improper fracture healing, especially in weight-bearing bones (e.g., ankle, foot, calcaneus). If the patient smokes, the fracture healing time in the ankle is doubled compared

to the nonsmoker. Colles' fracture healing may also be delayed in patients taking anti-inflammatory medications or smoking.

Among other factors, risk of *traumatic arthritis* is increased by the proximity of the fracture to a joint (especially if intra-articular), the forces causing the fracture (risk of damage to cartilage), repetitive fractures, and fracture healing.

# GANGLION TREATMENT

David T. Bortel

The most common tumor of the hand or wrist is the ganglion, which has a propensity for women. A ganglion can occur at almost any location adjacent to a joint or tendon sheath. The most common site is the dorsal wrist (Fig. 191-1), accounting for about 65% of ganglions; for this location the scapholunate ligament and joint are usually the source or root of the pathology (Fig. 191-2). Volar cysts account for about 20% to 25% of ganglions and typically originate from the scaphotrapezial or trapeziometacarpal joints (Fig. 191-3). Another site of origin is the palmar fibro-osseous flexor tendon sheath, which accounts for about 10% of ganglions. A ganglion at this location normally presents as a hard, small or pea-sized, painful lesion at the proximal interphalangeal flexion crease (Fig. 191-4). Ganglion cysts can be seen at other body sites, with the foot and ankle being common locations (Figs. 191-5 and 191-6). Occasionally they can even be found intraosseously.

#### **IDENTIFICATION AND CHARACTERISTICS**

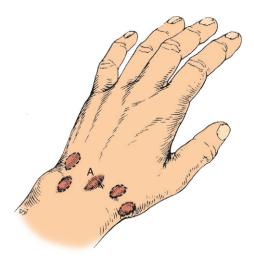

Patients usually present with an obvious mass and sometimes complain of pain and weakness. Ganglion cysts are usually easy to identify by their appearance. The most consistent characteristic is their location, as noted previously. The cyst is often rubbery, but it is sometimes firm. Occasionally a ganglion will allow fluid to be compressed from one septate area to another. The ganglion may transilluminate if it is of sufficient size. Seldom is it necessary to order additional studies to confirm the diagnosis; rather, confirmation is usually made by aspiration, which yields a viscous mucoid fluid (Fig. 191-7). A differential diagnosis includes extensor tenosynovitis, lipoma, sebaceous cyst, or other hand tumors.

The ganglion cyst is a fibrous-walled, mucin-filled structure typically connected to the joint capsule or tendon sheath by a tortuous stalk. In fact, it is basically a herniation of the synovial lining of tendons, ligaments, or joints. A "one-way valve" probably predicates

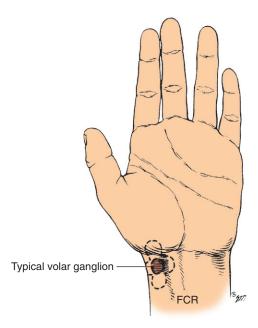

**Figure 191-1 Dorsal wrist ganglion.** (Courtesy of The Medical Procedures Center, Midland, Mich.)

the formation of these nonmalignant, yet frequently painful lesions. Use of the offending joint or tendon leads to increased production of the encapsulated mucin, thus magnifying the symptoms. The ganglion commonly is self-limiting (perhaps over several years) by rupture or resorption. These cysts may reflect an underlying ligamentous pathology.

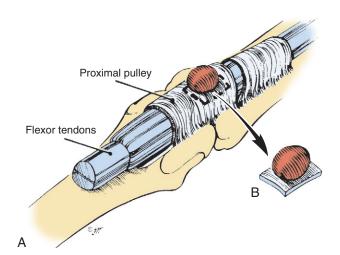

NOTE: A close "cousin" of the ganglion cyst is the mucous (or mucinous) cyst. Both are nearly identical histologically, but the mucous cyst often involves a more ominous process. Mucous cysts arise from an arthritic distal interphalangeal (DIP) joint (i.e., the cyst is a direct drainage conduit to the DIP joint; Fig. 191-8). Unfortunately, as these cysts enlarge with time, they will commonly erode into the germinal nail matrix, causing discomfort and nail distortion. (Nail distortion is a hallmark of this type cyst.) Past treatments have included sclerosis, steroid injection, electrical or chemical cautery, cryotherapy, and simple incision and drainage. The thinned local subcutaneous tissue may rupture spontaneously, leading to a septic joint or osteomyelitis. These lesions are particularly difficult to manage, even by skilled hand surgeons. Aspiration or injection of mucous cysts can be attempted judiciously, but the risk of causing a septic joint must be appreciated. If such treatment is implemented, the patient needs to be aware of the signs of infection.

**Figure 191-2** A few of the many possible locations of dorsal wrist ganglions. The most common site (A) is directly over the scapholunate ligament. The others are typically connected to the scapholunate ligament through an elongated pedicle. (Redrawn from Athanasian EA: Bone and soft tissue tumors. In Green DP, Hotchkiss RN, Pederson WC, Wolfe SW [eds]: Green's Operative Hand Surgery, 5th ed. Philadelphia, Churchill Livingstone, 2005, pp 2211–2264.)

# PREPROCEDURE PATIENT PREPARATION

The patient should be informed that he or she will experience some discomfort similar to having a tooth numbed by a dentist. When the area is being anesthetized, a temporary burning sensation is felt. The local anesthetic typically lasts for 30 to 60 minutes. While anesthetized, the involved tissue could be prone to further unknown trauma until the anesthetic subsides. After the procedure, there will be a pressure-like sensation that may last for a few days. Typically a pressure dressing will be necessary for several days over the ganglion site. Any steroid placed may produce a local reaction, which can be as simple as skin irritation or as dramatic as dermal atrophy, significant hypopigmentation, or subsequent cutaneous slough. Fortunately, the dramatic reactions are rare. Similarly, systemic manifestations are rare because dosages and volumes for these lesions are usually very small.

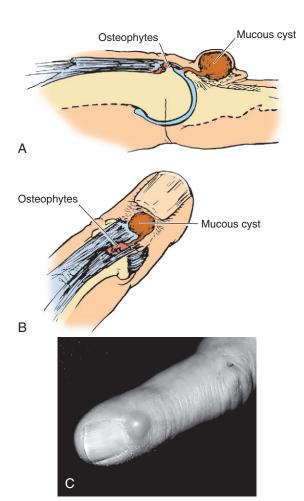

Ganglion cysts of the volar wrist near the distal radius are near the radial artery (Fig. 191-9). In fact, excision of a cyst in this region often requires dissecting scar tissue off the radial artery. Theoretically, incision and drainage of a ganglion in this area might predispose the patient to an arteriovenous malformation; however, a cyst that spontaneously ruptures in this area or is surgically removed may also predispose the patient to such a lesion.

# **Ganglion Cyst Excision**

The patient should be informed of the alternative to either simple observation or aspiration and injection, which is removal by a hand surgeon under regional or general anesthesia. Consequently, typical anesthetic risks should be discussed. The patient should be informed of additional risks of surgery of this nature, including infection, neurovascular injury, rarely a venous thromboembolic event (much more common in the lower extremities), or recurrence of the ganglion. If the ganglion has resulted from a capsular or ligamentous defect, additional problems such as underlying joint destabilization and stiffness may occur.

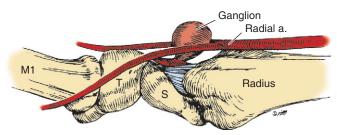

**Figure 191-7** Typical thick, honey-like consistency of ganglion mucin. (Courtesy of The Medical Procedures Center, Midland, Mich.)

# INDICATIONS FOR ASPIRATION AND INJECTION

- Symptomatic ganglion cyst (e.g., pain, paresthesias, motion limiting)
- Patient desires aspiration and/or injection (may be due to cosmetic deformity)

**Figure 191-9** Usual relationship of the ganglion to the radial artery and volar joint capsule. MI, first metacarpal; S, scaphoid; T, trapezium. (Redrawn from Angelides AC: Ganglions of the hand and wrist. In Green DP, Hotchkiss RN, Pederson WC [eds]: Green's Operative Hand Surgery, 4th ed. New York, Churchill Livingstone, 1999, pp 2171–2183.)

 Diagnosis uncertain (although rare, malignant lesions can mimic ganglion cysts)

# CONTRAINDICATIONS TO ASPIRATION AND INJECTION

Be cautious and consider anatomic locations for critical neurovascular structures. The radial artery and dorsal sensory radial nerve are notable vulnerable structures, and as such should be avoided.

#### **EQUIPMENT**

- 25- or 27-gauge needle, 1 mL or less of lidocaine (1%), without epinephrine, in 1 or 3 mL syringe (if local anesthesia to be used)
- 18-gauge needle and 3- or 5-mL syringe for aspiration
- 1- or 3-mL syringe filled with steroid if injecting
- Small (2 to 4 inch) elastic bandage (e.g., Ace wrap) (optional)

Please refer to specified treatment techniques. Also see Chapter 192, Joint and Soft Tissue Aspiration and Injection (Arthrocentesis).

# **TREATMENT (OPTIONS)**

- 1. Observation. Unless the ganglion is symptomatic (unsightly, painful, or limits motion), no treatment is necessary. Aspiration is indicated if there is uncertainty with the diagnosis.
- 2. Digital pressure or rupture with a mallet, large book (e.g., the Bible), or blade. These have all been tried historically with minimal success. Simple incision and drainage or rupturing with a needle are variants of this method.
- Aspiration and injection. Aspiration followed by a steroid injection remains a commonly used technique. Although recurrence rates are high (up to 33%), some consider it the initial treatment of choice.
- 4. Surgery. Excision may be simple or quite complex. It is generally performed with a sterile environment. Even though recurrence rate is low with surgery, it can be as high as 20% if the surgeon cannot remove the entire stalk and a portion of the joint capsule.

# TECHNIQUE FOR ASPIRATION AND INJECTION Steroids

- 1. Using a 25- or 27-gauge needle, 1 mL or less of local lidocaine (1%) without epinephrine is deposited in a wheal over the most superficial portion of the ganglion. If the cyst is small, avoid this step because it may obscure (i.e., make it difficult to palpate) the underlying lesion.
- 2. The clinician first stabilizes and localizes the ganglion by grasping it (or the area around it) between the thumb and index finger of the nondominant hand. Using the clinician's dominant hand, an 18-gauge needle attached to a 3- to 5-mL syringe is inserted centrally into the ganglion while aspirating. Entry into the cyst is confirmed by a flash (it may be a small amount) of gelatinous fluid into the syringe. All of the thick, gelatinous fluid is then aspirated (Fig. 191-10). Applying pressure on the cyst by squeezing it between the thumb and index finger of the nondominant hand may be helpful. (If no fluid is aspirated, yet the clinician is certain that the needle has entered the cyst, the needle has probably become obstructed with a skin plug or very viscous fluid. Withdraw and detach the needle, fill the syringe with air, and attempt to flush this air back through the needle with the needle directed into a biohazard bin. This may remove an obstruction caused by either a skin plug or clotted, viscous fluid. Reinsert the needle into the ganglion.)
- Secure this needle in place with a sterile hemostat (having verified that it is in the cyst) and remove the syringe filled with mucin.

**Figure 191-10** Use an 18-gauge needle and a 1- to 3-mL syringe to enter the ganglion and aspirate its contents. The contents are often thick, and there may be only minimal return of a gel-like material. Hold the needle in position with the hemostat and remove the syringe. Attach the steroid-containing syringe and inject the contents.

- 4. Attach another syringe (1 or 3 mL) filled with a 50/50 mixture of 1% lidocaine and steroid of choice (e.g., betamethasone; see Chapter 192, Joint and Soft Tissue Aspiration and Injection [Arthrocentesis]), and inject into the confines of the cyst. Variable amounts are used depending on the size of the cyst (0.1 to 1 mL). To reduce local steroid complications, consider starting with even smaller amounts of steroid. After injection, withdraw the needle.
- 5. Pressure is held over the needle track with a sterile gauze pad; then some clinicians wrap the area with a small elastic bandage (e.g., Ace wrap) to maintain occlusion of the cyst walls.
- 6. After successful aspiration, take all precautions to maintain the tip of the needle in the cyst until it is injected. After the cyst has been aspirated, if at all possible, do not withdraw the needle and then attempt a second insertion to inject (unless the needle becomes obstructed and has to be withdrawn to remove the obstruction).

#### **Sclerosants**

1. Technique is as noted for aspiration/injection. Instead of using steroids, substitute 1 mL of 3% sodium tetradecyl sulfate. This is the same solution used for sclerosing veins. Inject with approximately half the amount of the mucin withdrawn.

NOTE: This technique reportedly has an 80% resolution rate.

- 2. Maintain compression continuously for 2 weeks.
- 3. After successful aspiration, take all precautions to maintain the tip of the needle in the cyst until it is injected. After the cyst has been aspirated, *do not* withdraw the needle and then attempt a second insertion to inject.

# POSTPROCEDURE PATIENT EDUCATION

The patient should know to call the clinician's office or go to the emergency department for bleeding from the site, a significant increase in pain or fever, or signs or symptoms of infection. If a pressure dressing is applied, he or she should be instructed how to care for it and when it should be removed.

#### **COMPLICATIONS**

This procedure should *not* be taken lightly. Consideration of medical history and the location of the ganglion are of the utmost importance. The tissue overlying the ganglion commonly is thin with a poor blood supply and can slough because of bleeding, inadequate perfusion, or immune compromise. In addition, these cysts can be intertwined with neurovascular structures (see Fig. 191-9), and an intravascular or intraneural injection can have adverse results.

Subcutaneous atrophy or depigmentation can occur if the steroid concentration is too high.

#### **OPERATIVE TREATMENT**

Surgical excision usually is 95% curative if the ganglion and stalk are removed with a small cuff of the adjacent joint capsule. The procedure should be approached with the same seriousness as any other hand surgery. A surgical suite with general or regional anesthesia is preferred. These operations should be performed by clinicians familiar with these lesions and the nearby anatomic structures. Even with surgical excision, the cysts can recur. The small, troublesome mucinous cyst on the dorsal DIP joint can actually require a fairly aggressive procedure to resolve.

# JOINT AND SOFT TISSUE ASPIRATION AND INJECTION (ARTHROCENTESIS)

Thad J. Barkdull • Francis G. O'Connor • John M. McShane

Joint and soft tissue aspiration and injection are both clinically rewarding and relatively simple office procedures. Steroid injection into joints fell into disfavor for many years because the procedure was overused and abused. When appropriate guidelines are followed, however, complications are extremely rare, and the injections can be very beneficial to the patient by reducing symptoms. The alternative to focal treatment with injection is usually systemic nonsteroidal anti-inflammatory drugs (NSAIDs), which have significant toxicity with prolonged use.

Primary care physicians should master the technique of aspiration and injection for many reasons. If the physician aspirates an inflamed joint, a diagnosis can be made immediately. If a joint is distended, pain can be relieved rapidly by aspirating the fluid. Injecting an anesthetic or steroid solution can give focal pain relief without the toxicity of the systemic medications and provide valuable information regarding diagnosis.

The clinician should not withhold the benefits of injection therapy because of incomplete familiarity with the precise anatomy involved. Knowledge of soft tissue and bony landmarks provides a reliable method for identification of needle insertion sites. The emerging role of musculoskeletal ultrasound in office-based practice additionally offers new opportunities to improve diagnostic and therapeutic techniques. The reader may want to refer to Chapter 191, Ganglion Treatment, for related information.

#### **INDICATIONS**

#### **Diagnostic**

- To evaluate synovial fluid and determine whether an effusion is from an infectious, rheumatic, traumatic, or crystal-induced origin
- To perform a therapeutic trial to differentiate between various conditions (e.g., costochondritis vs. coronary artery disease, trochanteric bursitis vs. deep hip disease, occipital trigger points vs. vertebral disease)
- To differentiate an intra-articular from extra-articular origin of pain symptoms

# **Therapeutic**

- To remove exudative fluid from a septic joint
- To relieve pain in a grossly swollen joint (e.g., traumatic effusion)
- To reduce pain and inflammation by injecting lidocaine, with or without corticosteroids, or saline for trigger points (see Chapter 197, Trigger-Point Injection), noninfectious inflammatory arthritis, tendinitis, bursitis, or neuritis

 To stimulate the body's inflammatory cascade in order to promote healing (i.e., prolotherapy)

#### **Indications for Corticosteroid Injections**

Corticosteroids have a marked effect on inflammation. There are no good data to indicate that steroid injections decrease the long-term adverse effects of chronic degenerative osteoarthritis, but there is no doubt that they result in acute symptomatic improvement, especially over the first 1 to 4 weeks. The Cochrane Collaboration report on osteoarthritis supports the use of the intra-articular corticosteroids in the treatment of osteoarthritis (OA) of the knee.

Box 192-1 lists the conditions that are improved with local corticosteroid therapy. Localized pain that persists more than a few weeks after a trial of NSAIDs warrants an injection with steroids. Injections should be considered primarily when the potential toxicity or intolerance to NSAIDs outweighs the risk of local corticosteroids. Tramèr and colleagues noted in their meta-analysis that individuals chronically (≥2 months) using NSAIDs had a 1:1220 chance of dying from a gastrointestinal complication. In contrast, death occurring after intra-articular injections comes predominantly from septic arthritis, which occurs in anywhere from 1:3000 to 1:50,000 cases—with a mortality rate of about 15%. Morbidity risks associated with prolonged NSAID use are even greater.

## Indications for Hyaluronic Acid Supplementation

Synovial fluid functions as a lubricant and a shock absorber in the joint. In OA, it retains very little of these intrinsic physical properties. At a critical load, normal synovial fluid changes its mechanical properties from viscous lubricant to elastic shock absorber. This change occurs between walking and running and is determined by the dynamic stress of both the frequency and the force of the load—a property which is diminished in OA. In addition, the concentration of hyaluronan in the synovial fluid in patients with OA is less than normal. Injected hylans and hyaluronans have properties similar to normal synovial fluid, and although they may only remain in the knee less than 2 weeks, the beneficial effects can persist up to a year (mean duration of 8.2 months). There is some evidence that they stimulate endogenous production of the synovial fluid. There is no evidence that viscosupplementation retards the progression of joint deterioration, but a recent Cochrane Review concluded that viscosupplementation showed beneficial effects on pain and patient function; this modality shows promise of postponing for years the need for total knee replacement. Studies are ongoing to assess its efficacy in other joints, because it is currently only Food and Drug Administration (FDA)-approved for use in the knee. The materials injected (hylans and hyaluronans) are

pharmacologically inert so the FDA classifies them as "devices," not "drugs."

- Approved for use in knee only
- May be used instead of, or after, intra-articular corticosteroid injections and before surgical intervention
- Effective in all stages of OA of the knee, although it wanes in the most advanced stages
- Is being studied for use in other joints

# Indications for Prolotherapy

Prolotherapy is an alternative form of injection therapy, utilized by some clinicians to treat chronic musculoskeletal pain syndromes. *Prolo* is derived from proliferation, because the treatment causes the proliferation (growth and formation) of new connective tissue in

areas that have become weak. The concept behind this technique is to stimulate the body's own inflammatory cascade in order to promote reabsorption of unhealthy tissue, such as degenerative fibroblasts in injured tendons, and the creation of new, healthy tissue. Inflammation-promoting agents (>10% dextrose solutions, phenol- or sodium-morrhuate—containing solutions, autologous blood, platelet rich plasma [PRP]) are injected into the area of injury, often with the aid of ultrasound to best localize the target.

Prolotherapy is most often described in use with tendinopathy, and there is some evidence to suggest that it is an effective therapy in treating the degenerative tissues identified. The treatment most likely achieves its maximal benefit when coupled with physical therapy focused on further stimulating growth of new tendinous tissue. As prolotherapy is an emerging technique that can be highly operator dependent, those interested in providing this service are encouraged to consult with a prolotherapist or complete a course of instruction prior to beginning prolotherapy injections in an office practice.

#### **CONTRAINDICATIONS**

- Cellulitis or broken skin over the intended entry site for the injection or aspiration
- · Anticoagulant therapy that is not well controlled
- Severe primary coagulopathy
- Infected effusion of a bursa or a periarticular structure (for injection)
- More than three previous injections in a weight-bearing joint in the preceding 12-month period (*relative*—concern for theoretic joint destruction)
- Lack of response to two or three prior injections (*relative*)
- Suspected bacteremia (Unless the joint itself is suspected as the source of the bacteremia, it should not be tapped. Doing so could inoculate the joint space and cause infection.)
- Unstable joints (for steroid injection)
- Inaccessible joints (For many primary care physicians, this includes the hip joint, the sacroiliac joint, and the joints of the vertebral column.)
- Joint prostheses (If infection is suspected, consider a referral to the orthopedist that placed the prosthesis, if possible.)
- Pregnancy (relative)

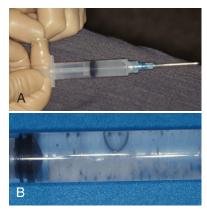

# **EQUIPMENT**

In the past, joint injections were frequently performed without gloves with only an alcohol wipe. In contrast, some physicians still use an extensive sterile draping procedure. Although the former is most likely inadequate, the latter is probably unnecessary unless the patient is immunosuppressed, diabetic, or at high risk of infection. Most injections are administered after an alcohol or povidone—iodine wipe. Gloves (sterile or nonsterile) should be used. When a culture is anticipated, sterile gloves are more customary. Masks are unnecessary.

Required equipment includes the following:

- Povidone–iodine wipes or alcohol wipes
- Sterile or nonsterile gloves
- Sterile drapes (optional)
- 22- to 27-gauge, 1½-inch needle for injections
- 18- to 21-gauge,  $1\frac{1}{2}$ -inch needle for aspirations
- 30-gauge, ½ -inch needle, if skin anesthesia is to be given (usually not needed)
- 1- to 10-mL syringe for injections (Luer-Lok is recommended.)
- 3- to 50-mL syringe for aspirations
- Single-dose vials of 1% lidocaine

**NOTE:** There are two reasons to use single-dose vials. First, no allergic reaction to lidocaine (an amide) has ever been reported. Although rare, reactions do occur to the preservative (parabens)

**Figure 192-1 A,** Example of precipitation of steroid (Celestone Soluspan) when mixed with lidocaine solution from a multidose vial. **B,** Steroid in solution (Celestone Soluspan) when mixed with lidocaine from a single-dose vial. It is preferable to have the steroid in solution rather than in precipitated form. (Courtesy of The Medical Procedures Center, PC, John L. Pfenninger, MD.)

that is used in multidose vials. Local anesthetics with an ester base (e.g., procaine [Novocain]) can cause allergic reactions. So, using a single-dose vial of lidocaine makes it highly unlikely that there will be a reaction. Second, many steroids will precipitate when mixed with the parabens preservatives. This leads to uneven distribution in the syringe as well as the injection of small crystals into the site, and these crystals themselves could cause an inflammatory process (Fig. 192-1). Theoretically, a homogeneous solution would be more efficacious, although no studies have looked at the issue and many feel it is a moot point and of little concern. Certain manufacturers, however, do not recommend injecting precipitated steroids.

Many practitioners will use a longer-acting local anesthetic such as bupivacaine (Marcaine). Although this addition in most cases will not have any untoward effects, it should be noted that there have been instances of myotoxicity associated with bupivicaine, and given that it is only intended to provide short- to medium-term relief of symptoms, one might question its regular use.

- Hemostat (to be used if joint is to be aspirated then injected using different syringes but same needle)
- Tubes for culture or other laboratory studies (if aspiration is performed)
- Corticosteroid preparation (Tables 192-1 and 192-2)

A reasonable rule of thumb is that the greater the water solubility of the corticosteroid, the more rapid the onset of action, and the shorter the duration of effect. Thus, steroids with a lower degree of water solubility would in general be more effective in a chronic disease process, such as OA, whereas an acute inflammatory process might be more responsive to a shorter-acting preparation (Table 192-3).

**NOTE:** It is best to pick out one or two preparations and learn them well. It is not necessary to be familiar with all the drugs listed. There is no consensus in the literature as to the "best" drug or the optimal dosages. Table 192-2 offers our recommendations for appropriate dosing.

- Hyaluronic acid preparation (if used)—sodium hyaluronate (Hyalgan, Supartz, Euflexxa, Orthovisc) and hylan G-F 20 (Synvisc and Synvisc-one); dosages are as follows:
  - Hyalgan: five injections, 1 week apart (\$691.60)
  - Supartz: five injections, 1 week apart (\$709.72)
  - Euflexxa: three injections, 1 week apart (\$599.15)
  - Orthovisc: three injections, 1 week apart (\$801.57)

TABLE 192-1 Relative Potency of Corticosteroids				
Corticosteroid	Relative Anti- inflammatory Potency	Approximate Equivalent Dose (mg)		
<b>Short-acting Preparations</b> Cortisone Hydrocortisone	0.8 I	25 20		
Intermediate-acting Preparation Prednisone Prednisolone tebutate (Hydeltra- TBA) Triamcinolone (Aristocort, Aristospan, Kenalog) Methylprednisolone acetate (Depo-Medrol)	3.5 4 5	5 5 4 4

- Synvisc: three injections, 1 week apart (\$813.96)
- Synvisc-one: one injection (\$375.00)
- Adhesive bandage dressing
- Ultrasound (see later discussion for information regarding ultrasound-guided injections and Chapter 185, Musculoskeletal Ultrasonography)

#### PREPROCEDURE PATIENT PREPARATION

Inform the patient of the risks, benefits, and possible complications of injection therapy. This information is especially important if steroids are used. Rarely is there ever a complication from the use of lidocaine alone. However, with steroids, and especially with repeated injections, there are some adverse consequences (see the "Complications" section and) Table 192-4. Inform the patient that there is always a possibility for infection with the injection, although this is extremely rare. Bleeding into a joint can occur, but this generally does not happen unless the patient has a coagulopathy. The injection may actually cause more pain during the first 24 to 36 hours. This reaction is called steroid flare. If the pain lasts for more than 72 hours, evaluate the patient for the possibility of a septic joint. Warn the patient of a possible failure to obtain relief, and that a second or even a third injection may be needed. Whether or not steroids have significant adverse effects on the cartilage and bone itself when steroids are injected into the joint space, and the degree of this reaction, is controversial. However, the effects would appear to be minimal, especially when used appropriately. Allergic reactions are very rare. Tendon ruptures should be avoidable if the injection is placed peritendinously instead of within the tendon itself. However, rupture is always a possibility. As a final precaution, warn the patient that a steroid placed too close to the surface of the skin occasionally causes atrophy (Fig. 192-2). This reaction may leave the patient with depigmentation and a slight indentation in the skin.

For diabetics, rapidly absorbed steroids can interfere with *glucose metabolism*. Therefore, glucose levels need to be followed more closely in the first 24 hours.

*Pneumothorax* has been reported after injection of trigger points and other conditions around the thorax. The following Technique section explains how to avoid this problem.

## **TECHNIQUE**

Before injection therapy, consider the differential diagnosis. If a tumor or fracture is possible, radiographs should be obtained. Many

Common Corticosteroids and Recommended Dosages for Various Joint Injections **TABLE 192-2** Concentration Small Joint<sup>†</sup> Ganglia Large Joint **Medium Joint** Tendon Bursa Corticosteroid Dosage (mg) Sheath (mg) (mg/mL) Dosage (mg) Dosage (mg) (mg) (mg) 20-50 Hydrocortisone acetate 25, 50 40-100 20-40 8-20 20-40 40-90 Prednisolone tebutate (Hydeltra-20 20-30 10-20 8-10 10-20 4-10 20 TBA) Prednisolone sodium phosphate 20 10-20 5-10 4–5 5-10 3-8 20 5, 20 10-20 8-10 10-20 4-10 20 Triamcinolone hexacetonide 20 - 30(Aristospan) Triamcinolone diacetate (Aristocrat) 25, 40 20-40 10-20 8-10 10-20 4-10 20 10, 40 20-40 10-20 20 Triamcinolone acetonide (Kenalog) 8-10 10-20 4-10 20, 40, 80 20-40 10-40 Methylprednisolone acetate (Depo-8-10 4-20 4-10 20 Medrol) 1 - 8.01 - 20.4-1 Dexamethasone sodium phosphate 1 - 32 - 3(Decadron) Dexamethasone acetate (Decadron-8 2-4 1 - 31 - 8.01 - 20.4 - 12-3 LA)

times, especially with trigger-point injection (see Chapter 197, Trigger-Point Injection), x-rays are unnecessary. Other diagnoses may also be fairly straightforward and not require a prior radiographic examination either. If the diagnosis is in question or if the patient is at risk for bone metastases (e.g., a history of breast or prostate cancer), the condition should be clarified before injection therapy.

Generally, the clinician injects a combination of lidocaine with the steroid of choice. Single-dose vials of lidocaine should be used to avoid the preservative/precipitation problems (see earlier comments and the "Complications" section). Using a rather large volume of lidocaine may be beneficial. Not only does it disperse the steroid in a less concentrated solution, the volume itself may have a therapeutic effect. In some instances, only a minimal amount of lidocaine can be used (e.g., ganglion cysts, trigger fingers). In other sites, larger amounts are recommended (e.g., lidocaine 5 to 10 mL in a shoulder or knee mixed with 0.5 to 1 mL of selected steroid). A good rule of thumb is to use more, not less, when it comes to lidocaine.

The recommended dosages of medications (Table 192-5) and the specific techniques for various injection sites (Figs. 192-3 to 192-25) are included in this chapter.

#### **General**

The general approach is as follows:

- 1. *Identify the site of entry* and mark it with a thumbnail, ballpoint pen, or indelible marker. Making a circular indentation at the designated site with the retracted end of a ballpoint pen is an excellent way to avoid losing your landmarks when cleaning the area.
- 2. Prep the area with an alcohol or povidone—iodine wipe. (Note that alcohol often removes ink and skin marker solutions.)

TABLE 192-3 Steroid Solubility

1.5-3

- 4. Note that although using smaller caliber needles may provide the patient with less pain, it is more difficult to determine whether the appropriate space for injection has been entered. In contrast, larger bore needles will be more painful. Based on the site of injection, and the constitution of the patient, you may decide to inject a superficial anesthetic (e.g., lidocaine) or use ethyl chloride spray on the skin prior to the intra-articular injection to allow for the use of a larger needle.
- 5. Using appropriate syringes and needles, either *aspirate* or *inject* the site as indicated. After insertion but before injection, pull back the plunger to be sure the needle is not in a blood vessel.
- 6. If aspiration of an effusion is to be followed by injection, there are two choices: (1) have two needle/syringe setups and enter the area twice, or (2) enter once, aspirate, grasp the needle with a hemostat (being careful not to change the position of the needle tip), remove the syringe with the aspirate, then replace it with the lidocaine/steroid syringe, and finally inject the contents.
- 7. If lidocaine or steroid is to be injected, it is often necessary to inject in two or three slightly different areas at the site of tenderness. This is not necessary when the joint space itself has been entered, although some practitioners advocate repositioning within bursal spaces because of the potential presence of

Such changes may take up to a year to resolve, and some can be permanent changes.

septations that may interfere with full dissolution within the desired area.

8. Although much has been written regarding *laboratory evaluation* of joint fluid aspirates, Schmerling and associates reported that the white blood cell (WBC) count and polymorphonucleocyte percentage (PMN) were the only helpful tests to determine the etiology of an exudate. Use lavender-topped Vacutainers for these studies. It is recommended that synovial fluid be examined within 1 hour after arthrocentesis. WBC counts of mildly inflammatory fluids can decrease to "noninflammatory range" within 5 to 6 hours. Glucose, protein, lactate dehydrogenase (LDH), complement fixation, electrolyte, uric acid levels, rheumatoid factor, and antinuclear antibodies were of little benefit. Fluids for chemistry testing if desired should be transported in green- or red-topped tubes and be analyzed within 4 hours.

If the exudate is cloudy, the WBC count is elevated, or a septic joint is strongly suspected, do not inject the area, and a *culture* is also indicated. For cultures, submit as much fluid as possible. "Swabbed samples" may not be adequate. Large-volume specimens (over 2 mL) support viability of most microorganisms for up to 24 hours at room temperature. Nevertheless, transport to the laboratory ASAP. *Do not refrigerate!* Large samples may be sent in the syringe used to aspirate them or in a sterile 5- or 10-mL container that has no additives (i.e., a red-topped glass tube). For volumes less than 2 mL, consider using bottles with culture media (e.g., Port-A-Cul) inside. Test tube containers with anticoagulant additives (i.e., lavender- or green-topped containers) should not be used.

If there is any suspicion of gouty arthritis, examine the fluid for crystals under polarized light.

A *peripheral smear* may be helpful when a bloody tap is obtained after trauma. The presence of fat cells indicates a fracture.

The Pfenninger articles listed in the bibliography contain many tables of other characteristics of synovial fluid for differential diagnosis, although the benefit of additional studies is unproved.

## Technique of Injection for Hyaluronic Acid "Devices"

- Must be intra-articular.
- More demanding than steroid intra-articular injections because it must be placed within the synovial space, not the surrounding soft tissue.
- Some will use fluoroscopy or ultrasound to be certain of intraarticular injection.
- Do not mix with lidocaine or steroids.
- Drain all effusions before injection.
- Forced injections push material into the elasticity zone and then
  are very difficult to administer; slow injections must be given with
  a 22-gauge or larger needle (which again may necessitate the use
  of superficial anesthesia with lidocaine or ethyl chloride spray to
  allow for better tolerance by the patient).

Anatomic Structure	Needle Gauge (Length)	Dose of 1% Lidocaine (mL)	Dose of Methylprednisolone Acetate (mg)
Abductor tendon of thumb (de Quervain's disease)	25 (1½ inch)	3–4	10–20

Wrist joint	22–25 (1–1½ inch)	2–4	20–40

Modified from Pfenninger JL: Injections of joints and soft tissue. Part II. Guidelines for specific joints. Am Fam Physician 44:1690, 1991.

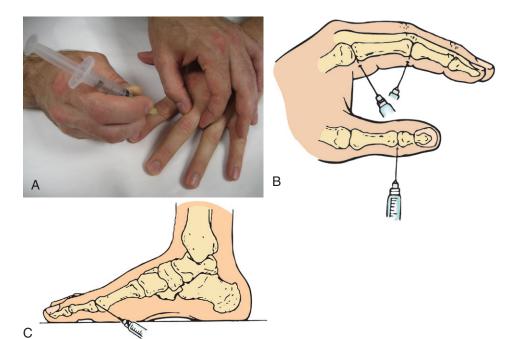

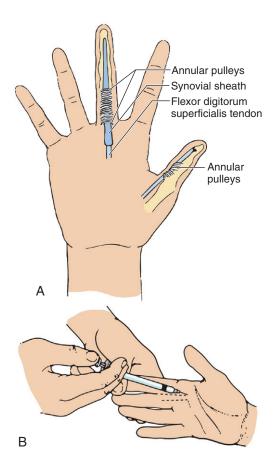

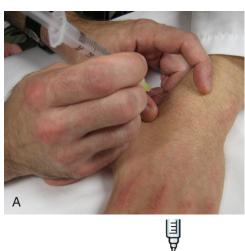

Figure 192-3 Injecting finger and toe joints. A, Appropriate technique for injecting a finger joint. Tendons run over the dorsum of the finger, whereas nerves and vessels run laterally. Open the joint slightly by flexing it and then inject between the ligaments and the vascular structures as noted. The needle enters at a 45-degree angle to the joint. Any of the finger (B) and toe (C) joints may be aspirated or injected in the lateral or medial aspect. Slightly flex the joint to open the joint space. Direct the needle to enter just medial or lateral to the extensor tendon, avoiding too lateral or medial an approach where the nerve and vascular structures run. Use a 25-gauge, 1-inch needle with 0.5 to 1.0 mL 1% lidocaine and 4 to 10 mg of methylprednisolone acetate or equivalent (see Tables 192-2 and 192-5).

**Figure 192-4** Trigger finger. **A,** The anatomy of a finger showing the annular pulleys, which maintain the flexor close to the bony structures. When the tendon becomes inflamed and enlarges, it catches on the pulleys, causing a snapping with extension or a "trigger finger." **B,** Identify the flexor tendon involved. Insert the needle at the distal palmar crease. Attempt to position it peritendinously. When the needle is in position, the syringe will move with flexion of the finger. Use a 25-gauge, 1-inch needle with 0.25 to 0.5 mL 1% lidocaine and 4 to 10 mg of methylprednisolone acetate or equivalent (see Tables 192-2 and 192-5).

**Figure 192-5** Wrist joint. **A,** Injection of the wrist joint. The hand is held in slight flexion, and the needle is inserted just distal to the radius in the "snuff box." **B,** Flex the joint 20 degrees to open the joint spaces. The dorsal approach is generally used. Position the needle perpendicular to the skin surface. Enter at a site distal to the radial head and lateral to the extensor pollicis longus tendon (just ulnar to the anatomic "snuff box"). If the needle can be easily inserted to 1 or 2 cm, it is correctly positioned in the joint space. The intercarpal joints have interconnecting synovial spaces, and the contents of one correctly placed injection will disperse into the entire joint complex. Use an 18- to 20-gauge, 1- to  $1\frac{1}{2}$ -inch needle with 0.5 to 1.0 mL 1% lidocaine and 4 to 10 mg of methylprednisolone acetate or equivalent (see Tables 192-2 and 192-5).

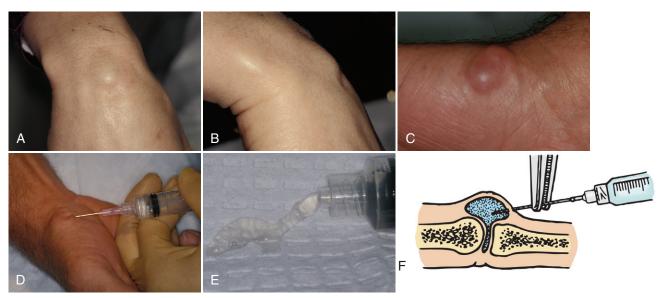

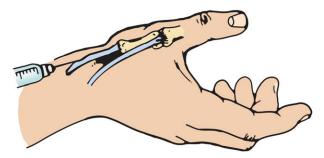

Figure 192-6 A ganglion is a manifestation of joint inflammation. **A,** Frontal view. **B,** Side view. **C,** Example of an unusual ganglion cyst on the thenar eminence. **D,** Aspiration of the cyst. Hold the needle in position with the hemostat and remove the syringe. Attach the steroid-containing syringe and inject the contents. (Some have used fibrin sealants, hypertonic saline, and other irritants for attempts to "scar down" the cyst.) **E,** The contents are often thick, and there may only be minimal return of a gel-like material. **F,** Use an 18- to 20-gauge, 1- to 1½-inch needle with 0.5 to 1.0 mL 1% lidocaine and 4 to 10 mg of methylprednisolone acetate or equivalent (see Tables 192-2 and 192-5). (**A–E,** Courtesy of The Medical Procedures Center, PC, John L. Pfenninger, MD.)

- Patient should avoid strenuous activity for 48 hours.
- Derived from chicken or rooster combs, so an allergy to eggs or feathers would dictate caution.

## **Technique of Injection for Prolotherapy**

A complete course of instruction prior to beginning prolotherapy injections in an office practice is recommended.

- Typically used in areas of degenerative tissue (i.e., tendinoses).
- Because of common usage with tendinous tissues, care must be taken to inject into the peritendinous areas rather than into the body of the tendon itself.
- Ultrasound can be considered to confirm placement of agent into the desired area.
- Because an inflammatory response is the desired outcome, educating the patient regarding anticipated pain over the next 24 to 48 hours is strongly encouraged. Some practitioners even advocate the use of opioid analgesics for pain control in the immediate postinjection period.

**Figure 192-7** De Quervain's disease. Maximally abduct the thumb to accentuate and identify the tendon. Insert the needle parallel to (but not into) the tendon. Inject at the areas of greatest tenderness. Postinjection splinting may still be necessary. Use a 25-gauge,  $1\frac{1}{2}$ -inch needle with 3 to 4 mL 1% lidocaine and 10 to 20 mg of methylprednisolone acetate or equivalent (see Tables 192-2 and 192-5).

- There are no current recommendations for the ideal proinflammatory agent; availability (i.e., dextrose solutions) or desire to utilize the patient's own fluids (i.e., autologous blood, plateletrich plasma) are two of the considerations made in determining the appropriate agent.
- Lidocaine should be injected to provide local anesthesia prior to using the other agents.
- Volume of agent should be based on the size of the area involved most tendinous injections usually require no more than 5 mL of solution. Some areas will allow for a greater volume to be placed, but may cause more postinjection pain.
- Although there is no consensus as yet for the appropriate interval
  or total number of injections that should be administered, it is
  reasonable to wait at least 4 to 6 weeks between treatments. If
  more than five injections are necessary, consideration should be
  made for other therapies.

#### **Ultrasound Guidance for Injections**

Also see Chapter 185, Musculoskeletal Ultrasonography.

Ultrasound is an extremely valuable modality that can allow the physician to identify the structure to be injected and guide the needle to its precise location. This can be particularly beneficial in reducing the pain associated with "blind" localization of small joint spaces, making the patient more comfortable, and thus more compliant, during the procedure.

Ultrasound-guided injections also allow the clinician greater confidence in interpreting the results of an injection. For example, a missed injection into the acromioclavicular joint may suggest another etiology of a patient's shoulder pain, resulting in further erroneous testing and treatment regimens unless the error is identified on ultrasound. When the injection is performed with ultrasound, the physician has objective evidence of appropriate placement of the medication and can therefore derive more accurate conclusions regarding the efficacy of the medication.

In order to perform ultrasound-guided injections, the physician must have some training in the use of diagnostic ultrasound. The machine used should ideally have at least one multifrequency transducer, in order to allow for visualization of both superficial and

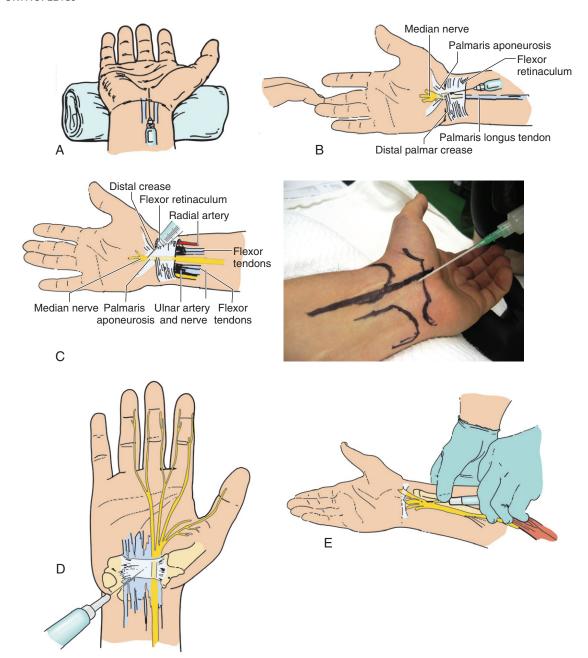

Figure 192-8 Carpal tunnel syndrome. Four approaches to injection: **A**, *Traditional method*. Dorsiflex the wrist 30 degrees and rest it on a rolled towel. Insert the needle at the distal crease of the wrist either lateral or medial to the palmaris longus tendon. **B**, Find the tendon by having the patient flex the middle finger against resistance or abduct the thumb and little finger together. Angle the needle downward at a 45-degree angle toward the tip of the middle finger. If there is any discomfort in the fingers, withdraw and reposition the needle. Advance I to 2 cm until there is *no* resistance, and then inject the medication. **C**, *Alternative method* (illustrated and pictured). Insertion of the needle directly over the carpal tunnel. Use a perpendicular approach going directly through the flexor retinaculum into the median nerve space. **D**, A third method of injecting the carpal tunnel. The needle is inserted just radial to the pisiform bone and directed toward the carpal tunnel just beneath the transverse carpal ligament. The needle goes dorsally and distally to terminate within the carpal tunnel just to the ulnar side and dorsal to the median nerve. **E**, A more recent approach is to inject on the volar aspect of the forearm 4 cm proximal to the wrist crease between the palmaris longus tendon (see previous description) and the radial flexor tendon. The needle is inserted in a distal direction with the syringe lifted I0 to 20 degrees up from the parallel. This approach supposedly minimizes chances of trauma to the nerve. In all cases (A–E), the injection should be given with minimal pressure, slowly. If there is resistance or if the patient feels "pins and needles" in the fingers, stop immediately. If an intraneural injection occurs, there will be significant pain after injection and surgical decompression may be needed. Use a 25-gauge, I½-inch needle with I mL 1% lidocaine and 20 to 40 mg of methylprednisolone acetate or equivalent (see Tables 192-2 and 192-5).

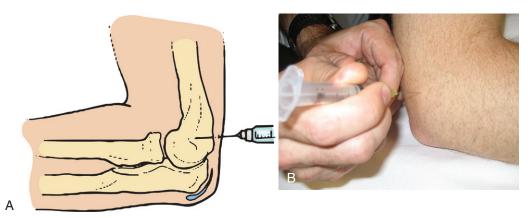

Figure 192-9 Lateral epicondylitis (tennis elbow). A and B, Find the area of greatest tenderness over the lateral epicondyle. Insert the needle perpendicularly until bone is felt. Withdraw the needle I to 2 mm and inject. It may be beneficial to fan out the injections in several directions into the extensor aponeurosis and the radial collateral ligament. Massage the injection site. If distal tenderness is still present after several minutes, another injection in a fanlike pattern may be necessary. Medial epicondylitis (golfer's elbow) is treated in a similar fashion. Use a 22- to 25-gauge, I/2-inch needle with 3 to 5 mL 1% lidocaine and 10 to 30 mg of methylprednisolone acetate or equivalent (see Tables 192-2 and 192-5).

Figure 192-10 Olecranon bursa, aspiration and injection. **A,** An enlarged bursa secondary to bursitis. **B,** Aspirating the olecranon bursa. This bursa is easily identified and entered. **C,** Insert a large-bore needle directly into the bursa and aspirate until fluid is returned. Whether cloudy or not, the fluid should be submitted for culture and concurrent infection should be ruled out. Await the culture results before injecting with a steroid. It is next to impossible to tell whether the bursa is infected or not on a clinical basis. While waiting for the culture results, place the patient on nonsteroidal anti-inflammatory drugs (NSAIDs) and wrap the area tightly. If infection is suspected, start an antibiotic to cover gram-positive pathogens while waiting for culture results. Once infection is ruled out, steroids can be used. In a double-blind study comparing focal steroid injection into the olecranon bursa with systemic NSAIDs, the most rapid benefit and most lasting effect came from steroid injections. Use an 18- to 21-gauge needle for aspiration. Use a 22-gauge, 1- to 1½-inch needle with 2 to 3 mL 1% lidocaine and 10 to 20 mg of methylprednisolone acetate or equivalent for injection (see Tables 192-2 and 192-5). (Courtesy of The Medical Procedures Center, PC, John L. Pfenninger, MD.)

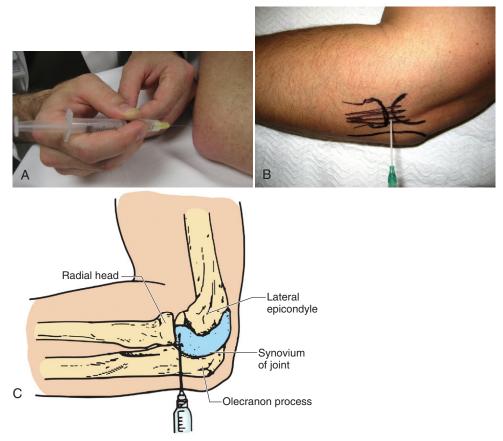

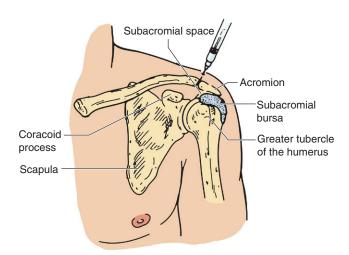

Figure 192-11 Elbow joint. **A,** Injection of the elbow joint. **B,** Flex the elbow 45 degrees. Identify the lateral epicondyle. Inject into the joint space just distal to the lateral epicondyle and superior to the olecranon process of the ulna. A slight concavity can be felt just inferior to the radial head and helps identify the proper point of insertion. **C,** Use a 22-gauge, I- to I/<sub>2</sub>-inch needle with 3 to 5 mL 1% lidocaine and 20 to 30 mg of methylprednisolone acetate or equivalent (see Tables 192-2 and 192-5).

**Figure 192-12** Acromioclavicular joint. With the patient seated and arm at the side, palpate the clavicle, moving laterally until a prominence is felt. This is the acromioclavicular joint. It is about 1.5 to 2 cm inward from the lateral edge to the acromion. Insert the needle from an anterior or superior position into the joint and angle it medially, then inject. Use a 22-gauge, I to  $1\frac{1}{2}$ -inch needle with 5 to 7 mL 1% lidocaine and 30 to 40 mg of methylprednisolone acetate or equivalent (see Tables 192-2 and 192-5).

deeper structures. Power Doppler capability is also valuable because it allows the physician to avoid vasculature and to better observe the flow of the medication in the actual space intended.

When performing ultrasound-guided injections, the following supplies are needed:

- Ultrasound gel
- Antiseptic, such as alcohol or Betadine
- Gauze pads and adhesive bandages
- Ethyl chloride spray
- Syringes (It is important to ensure that all air has been cleared out of both the needle and the syringes to be used, because air bubbles obscure ultrasound images.)
- Needles of appropriate length to reach the target
- A pair of forceps or a needle holder

The standard technique for performing therapeutic injections under ultrasound guidance is as follows:

- With the patient in a comfortable position, place some ultrasound gel over the area to be visualized and then use the ultrasound transducer to identify the structure to be injected.
- 2. Once the structure has been identified, place the transducer so that its long axis will be parallel to best line for the needle to take in order to reach its target (Fig. 192-26).
- Use appropriate antiseptic solution to cleanse the skin at the end of the transducer where the needle will enter. Be sure not to move the transducer once the skin has been prepared.
- 4. Use the ethyl chloride spray to superficially anesthetize the skin that will be punctured by the needle.

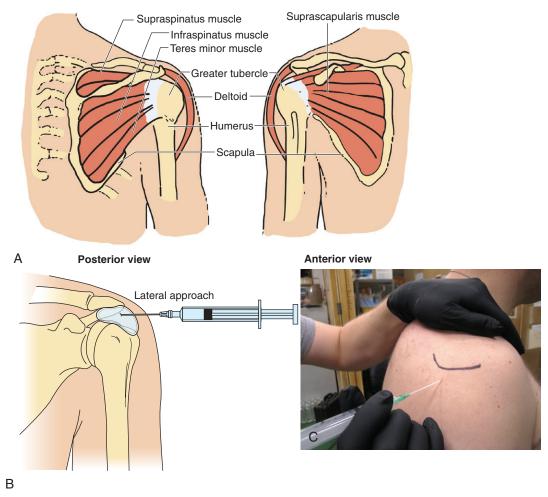

Figure 192-13 Shoulder: Subacromial bursa. Most injection procedures involving the shoulder will include an injection into the subacromial bursa. Palpate the superior surface of the shoulder, progressing laterally until there is a slight drop-off. This is the lateral edge of the acromion. The now palpable soft spot above the humeral head is the location of the subacromial bursa. Direct the needle perpendicular to the surface and insert the needle through the deltoid muscle into the bursa. The needle should be free floating, since it is within a space, not in a muscle or tendon. The tendon of the supraspinatus, the muscle most commonly involved in a rotator cuff syndrome, is directly medial to this bursa and can be entered by directing the needle deeper. If the tendon is calcifled as it is entered, a gritty sensation may be felt. Inject within the bursa, not within the tendon. **A,** The muscles of the rotator cuff are demonstrated. They include the supraspinatus, the infraspinatus, teres minor, and the subscapularis. **B,** The technique of a subacromial bursa injection. **C,** Injecting the subacromial bursa. Use a 22-gauge, I- to  $1\frac{1}{2}$ -inch needle with 5 to 7 mL  $1\frac{1}{2}$  lidocaine and 30 to 40 mg of methylprednisolone acetate or equivalent (see Tables 192-2 and 192-5). (**B,** Courtesy of Pharmacia Corp.)

- 5. Take the needle and syringe containing the local anesthetic and hold it parallel to the ultrasound transducer with the tip of the needle aimed at the skin that has been cleansed. Keeping the needle constantly parallel to the transducer, enter the skin and inject a small amount of anesthetic.
- 6. Using the ultrasound transducer, constantly keep the needle and the target to be injected in view. As the needle is advanced, repeatedly inject a small amount of anesthetic ahead of the tip. The fluid injected will be seen distending the tissue, and will help establish the location of the needle. If the needle is moved off target, slightly withdraw and redirect toward the target.
- 7. Once the structure to be injected is reached, turn on the power Doppler and center it over the tip of the needle. Inject some anesthetic into the targeted area and watch for flow on the Doppler. If the needle is placed accurately, it will be confirmed by seeing flow on the Doppler in the desired location.
- 8. Once the location of the needle is confirmed, the needle is held in place by the forceps/needle holder and the syringe is removed. The syringe containing the fluid to be injected is then attached to the needle and the fluid is then injected.
- 9. The needle is withdrawn, pressure is placed over the puncture site, and an adhesive bandage is placed.

#### **COMPLICATIONS**

Box 192-2 lists the possible complications of intra-articular or soft tissue injections. Also see Table 192-4.

Possible complications include the following:

 Injection into a vein or artery (This rarely causes a problem except that the therapeutic effect may not occur. Lidocaine and steroids are both given intravenously for other conditions.)

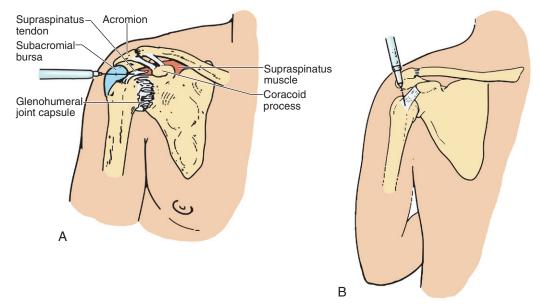

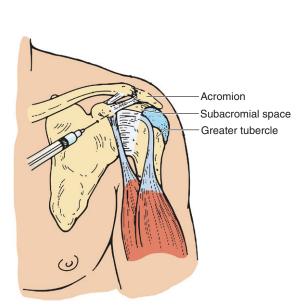

Figure 192-14 Shoulder: Rotator cuff (supraspinatus tendinitis). **A,** Use the same approach as that used for injecting the subacromial bursa (see Fig. 192-13). However, insert the needle deeper to reach the peritendinous area. **B,** Alternatively, have the patient rotate the flexed arm behind the back. Palpate the inferior edge of the acromion. The greater tuberosity of the humerus lies just below it. The tendon lies in the hollow between these two bones. Use an 18- to 20-gauge, 1½-inch needle with 5 mL 1% lidocaine and 20 to 40 mg of methylprednisolone acetate or equivalent (see Tables 192-2 and 192-5).

**Figure 192-15** Shoulder: Short head of the biceps. The short head of the biceps attaches to the coracoid process. This is the palpable bony prominence located inferior to the clavicle and medial to the humerus over the anterior portion of the shoulder. Rarely does this area have to be injected, but should a patient have pain and discomfort over the coracoid process, insert a needle directly into the point of maximal tenderness until it reaches the bone. Withdraw the needle I or 2 mm and inject. Only a small volume of steroid is needed along with relatively larger amounts of lidocaine. Additional steroid may be injected parallel to the tendon distally (if it is palpable). Use a 22-gauge,  $1\frac{1}{2}$ -inch needle with 5 to 10 mL 1% lidocaine and 10 to 20 mg of methylprednisolone acetate or equivalent (see Tables 192-2 and 192-5).

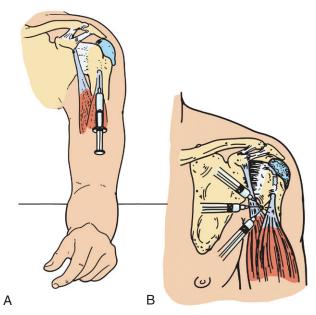

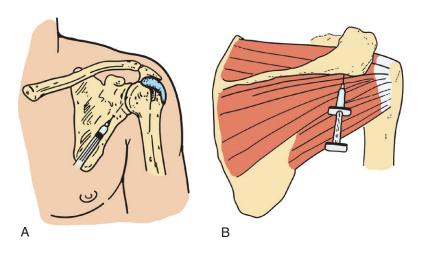

Figure 192-16 Shoulder: Bicipital tendinitis (injection of the long head of the biceps tendon). A, Have the patient seated with arm flexed 90 degrees. Identify the biceps tendon by placing your hand on the patient's shoulder with your fingers posteriorly and the thumb anteriorly over the proximal humerus. Internally and externally rotate the patient's arm. The bicipital groove is palpable anteriorly and the tendon "snap" can be felt under your thumb. Identify the most tender area of the tendon (usually in the bicipital groove on the humerus). Insert the needle into this groove and attempt to make a peritendinous injection of steroid and lidocaine. Often, a slip of the subacromial bursa surrounds the more proximal portion of the tendon. B, If pain persists on palpation after the injection, further injection in a fanlike peritendinous pattern may be needed more distally. Use a 22-gauge, 1½-inch needle with 5 to 10 mL 1% lidocaine and 10 to 20 mg of methylprednisolone acetate or equivalent (see Tables 192-2 and 192-5).

Figure 192-17 Shoulder: Intra-articular shoulder joint injection. A posterior or an anterior approach can be used to inject into the space of the shoulder joint (scapulohumeral or glenohumeral joint). A, In the anterior approach, externally rotate the shoulder. This movement opens the joint space. Identify the coracoid process. Insert the needle I cm inferior and I cm lateral to the coracoid process, and direct the needle perpendicularly, or slightly laterally, into the glenohumeral joint. The properly inserted needle should not contact bone. B, With the posterior approach, the patient is again seated with the arm internally rotated across the waist. Palpate the inferoposterior aspect of the acromion with the thumb. Place the index finger on the coracoid process. Insert the needle just below the acromion and aim toward the coracoid. Insert 2 to 3 cm deep. Use a 20-gauge, I/2-inch needle with 5 to 7 mL 1% lidocaine and 20 to 40 mg of methylprednisolone acetate or equivalent (see Tables 192-2 and 192-2).

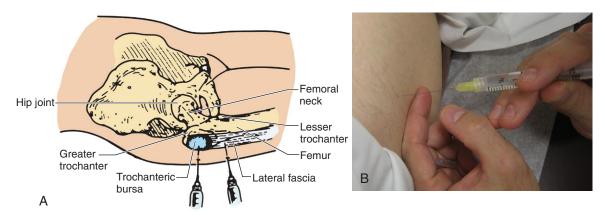

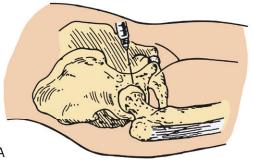

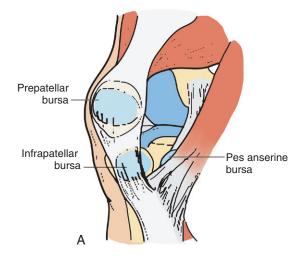

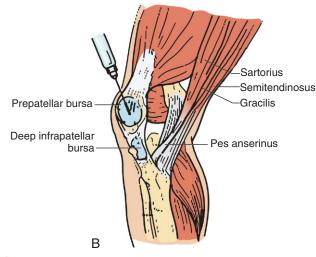

Figure 192-18 Trochanteric bursa. **A,** Trochanteric bursa is located at the most superior prominent portion of the femur. A bony prominence can be palpated. Tenderness in this area generally denotes trochanteric bursitis. Direct the needle perpendicular to the femur at the point of maximal tenderness, and insert until bone is felt. Withdraw the needle 2 to 3 mm and inject. Frequently the pain will radiate more distally (as it might with lateral epicondylitis in the arm) down the lateral portion of the femur along the fascia. If the patient is still experiencing discomfort 5 minutes after injection of the bursa and massage of the area, a more distal injection may be necessary at the areas of tenderness. **B,** Injecting for trochanteric bursitis. Use a 22-gauge,  $1\frac{1}{2}$ - to 2-inch needle with 5 to 10 mL 1% lidocaine and 20 to 40 mg of methylprednisolone acetate or equivalent (see Tables 192-2 and 192-5).

**Figure 192-19** Hip joint proper. **A,** Experience is necessary to inject the hip joint itself. Even experienced practitioners often use fluoroscopy. An anterior or posterior approach can be taken. However, the anterior approach is most common. Great care must be taken to avoid entering any of the blood vessels or nerves coursing through the inguinal canal area. Position the hip so that the leg is maximally extended and internally rotated. Use a long needle to enter 2 to 3 cm below the anterior superior spine of the ilium and 2 to 3 cm lateral to the femoral pulse. The needle should point posteromedially at a 60-degree angle to the skin and then should course through the capsule ligaments until it reaches bone. Withdraw the needle slightly and aspirate for fluid. Injection may then be carried out, and there should be little resistance. **B,** Injecting the hip. Use a 20-gauge,  $2\frac{1}{2}$ - to 3-inch needle with 5 mL 1% lidocaine and 40 to 80 mg of methylprednisolone acetate or equivalent (see Tables 192-2 and 192-5).

**Figure 192-20** Prepatellar bursa. **A,** Identify the bursa, which is located between the skin and the patella. **B,** Insert the needle just above the patella and at the lateral portion of the bursa, and direct it to the center of swelling. Aspirate fluid (for culture), switch syringes, and then inject. (Although the data are not as documented as for olecranon bursitis, the protocol for injecting this bursa can be the same.) Use a 20- to 22-gauge, I- to  $1\frac{1}{2}$ -inch needle with 3 mL 1% lidocaine and 20 to 40 mg of methylprednisolone acetate or equivalent (see Tables 192-2 and 192-5).

- Introduction of infection (usually Staphylococcus) into joint space (18 infections per 250,000 injections [0.072%])
- Trauma to articular cartilage
- Injury to nearby nerves (e.g., median nerve in carpal tunnel injection)
- Pneumothorax (when injecting thoracic trigger points)
- Subcutaneous fatty atrophy (see Fig. 192-2)
- Adverse drug reaction (see Table 192-4)
- Injection of steroid into a septic joint (If there is any suspicion of infection, do not instill steroids until laboratory studies have ruled it out.)
- Osteoporosis and cartilage damage (This is rare; reported cases have usually occurred after 20 to 30 injections. For joints, especially weight-bearing joints, a limit of three steroid injections per year provides a wide margin of safety.)
- Inappropriate/missed diagnosis

- Tendon rupture (To reduce the possibility of tendon rupture, inject peritendinously instead of intratendinously. Ruptures usually occur after multiple injections and when the patient will not rest the area. Finger tendon ruptures have been reported after steroid injection. Gray and Gottlieb recommend setting a limit of five total injections per finger joint.)
- Reactions to anesthetic agent (True allergic reactions to lidocaine (an amide) itself have not been reported. Allergic reactions have been reported to the esters [e.g., procaine/Novocain]; when reactions to lidocaine are suspected, the lidocaine has usually been drawn up from a multidose vial. These vials contain parabens preservatives, which can cause a reaction. So, if suspicions of a "caine" allergy arise, single-dose vials of lidocaine should be used. Another reason to use single-dose vials is to avoid precipitation of the steroid; see earlier discussion.)
- Steroid flare (Steroid flares occur rarely but are very painful. The
  patient actually experiences more discomfort after the injection.
  The flare is not associated with fever, occurs within 12 to 24 hours
  of the injection, and resolves spontaneously within 72 hours. It
  may be controlled with ice and nonsteroidal drugs.)
- Problems with viscosupplementation injections
  - Injection site pain is more frequent.
  - Rash and itching, cramps, ankle edema, muscle pain, and tachyarrhythmia have been reported.
  - A local reaction can produce a massive effusion that resembles a septic joint; 69% with pain experience relief after effusion resolves.

## POSTPROCEDURE PATIENT CARE AND EDUCATION

- An adhesive bandage dressing or other dressing should be left on for 8 to 12 hours.
- It is essential that the affected area be rested. Injection therapy is not a cure itself. It is used in conjunction with other modalities. Physical therapy, NSAIDs, and hot or cold compresses may all be indicated, depending on the specific problem. If a weight-bearing joint (such as the knee) is injected, rest is indicated for a longer period than that for a wrist ganglion cyst injection.
- The patient should report immediately if he or she develops fever, chills, or any sign of infection. If the discomfort from the injection does not resolve within 72 hours, the patient should be examined to rule out a septic joint.
- The patient may bathe normally.
- A short course of an NSAID is often beneficial at the time of injection; the two modalities combined may have a markedly beneficial effect.

#### **CONCLUSION**

A practitioner who is appropriately familiar with the indications and methods for joint and soft tissue injections and aspiration can better diagnosis and treat a number of conditions. The overall incidence of significant side effects is small when proper selection of the patient and technique are utilized.

Indications and techniques for injections are expanding, as are the medications incorporated. Growing interest has developed around the use of botulinum toxin in certain conditions, as well as consideration of NSAIDs intra-articularly to obviate the side effects that limit corticosteroid use. These modalities provide an opportunity for the primary care physician to either diagnose or treat debilitating conditions, and oftentimes to prolong the time to or alleviate the need for more invasive procedures.

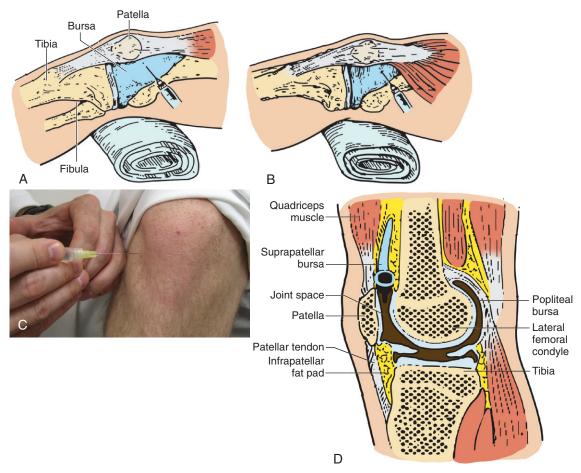

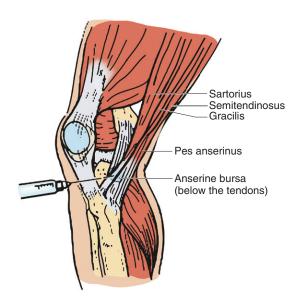

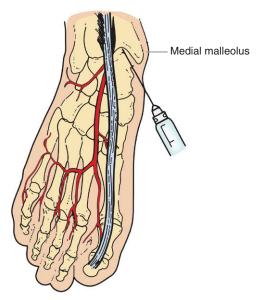

Figure 192-21 Knee joint. The knee is one of the easiest joints to enter and one of the most common joints to aspirate and inject. Slightly flex the knee using a towel in the popliteal space with the patient lying on an examination table. Either a lateral (**A**) or medial (**B**) approach may be used. For the lateral approach, palpate the superior lateral aspect of the patella and insert the needle 1 cm superior and 1 cm lateral to this point. Apply gentle pressure on the contralateral side of the knee to encourage the fluid to pool in the area of aspiration. Direct the needle under the patella at a 45-degree angle to the midjoint area. Aspirate all fluid before injection. There should be no resistance. **C**, Other approaches include entering medially or laterally directly above the joint line with the patient seated, or going directly through the patellar tendon just below the patella. **D**, The knee joint space is large and is readily entered from multiple approaches. Use a 20-gauge, 1- to 1½-inch needle with 5 mL 1% lidocaine and 20 to 80 mg of methylprednisolone acetate or equivalent (see Tables 192-2 and 192-5).

A Baker's cyst is a sac of synovial fluid that has leaked out of a hole in the posterior capsule of the knee. It generally indicates significant internal knee problems, and steroid injections are only a temporary relief frowned on by many clinicians. Insert the needle 3 cm medial to the midline and 3 cm below the popliteal crease. Take care to avoid the popliteal artery, vein, and nerve. Use a 20-gauge, I to  $1\frac{1}{2}$ -inch needle with 5 mL 1% lidocaine and 20 to 80 mg of methylprednisolone acetate or equivalent (see Table 192-2).

**Figure 192-22** Anserine bursa. The anserine bursa is located on the upper medial portion of the tibia under the insertion of the sartorius, semitendinosus, and gracilis tendons. This bursa frequently becomes inflamed in elderly, somewhat obese women; the symptoms are aggravated by going up and down stairs. Palpate and find the point of maximal tenderness, and insert the needle perpendicular to the tibia. When bony resistance is encountered, withdraw the needle 2 or 3 mm and inject several areas in a fanlike fashion. Use a 22- to 25-gauge,  $1\frac{1}{2}$ -inch needle with 3 to 5 mL 1% lidocaine and 20 to 40 mg of methylprednisolone acetate or equivalent (see Tables 192-2 and 192-5).

**Figure 192-23** Ankle joint. Anteromedial approach is the easiest. Have the patient maximally dorsiflex the toe, accentuating the extensor tendon. Identify the hollow between the anterior medial malleolus and the long extensor tendon. This is the spot for injection. The needle must be inserted approximately 3 cm and directed slightly lateral. Use a 22-gauge, I- to  $1\frac{1}{2}$ -inch needle with 3 to 5 mL 1% lidocaine and 20 to 40 mg of methylprednisolone acetate or equivalent (see Tables 192-2 and 192-5).

\*Can also charge for any injected medications using appropriate J code.
†Office visit can also be charged.

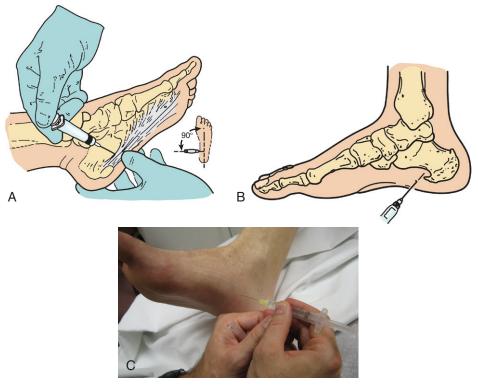

Figure 192-24 Calcaneal spur/plantar fasciitis. Two approaches can be used. Many physicians prefer to direct the needle from the lateral side of the foot (A) rather than from the inferior (plantar) side (B). The adipose tissue of the heel is uniquely segmented to provide cushion for the foot. If the plantar approach is used and steroid leaks out through the tract, atrophy could result, and thus the patient would have heel pain while walking. Nevertheless, many physicians approach directly from the plantar position to inject steroid right over a calcaneal spur. Using the lateral approach, the physician would direct the needle to enter just below the bony prominence of the calcaneus, and just anterior to the heel pad, and go to the midline until the point of maximal tenderness is reached (C). Use a 22-gauge, 1½-inch needle with 2 to 4 mL 1% lidocaine and 15 to 30 mg of methylprednisolone acetate or equivalent (see Tables 192-2 and 192-5).

**Figure 192-25** Morton's neuroma. Approach the foot from dorsal aspect. Insert needle 1 to 2 cm proximal to affected web space. Insert needle perpendicularly all the way to the plantar surface. Do not penetrate skin, but estimate depth by observing tenting of skin. Withdraw 1 cm and inject. Use a 25-gauge,  $1\frac{1}{2}$ -inch needle with 3 to 5 mL 1% lidocaine and 10 to 30 mg of methylprednisolone acetate or equivalent (see Table 192-2).

# Box 192-2. Possible Complications of Intra-articular or Soft Tissue Injections

#### **Local Complications**

Bleeding

Charcot-like arthropathy

Fat necrosis

Hemarthrosis

Iatrogenic infection; septic arthritis

Intra-articular calcification

Nerve damage from inadvertent injection

Osteonecrosis

Pain

Periarticular calcification

Pneumothorax (thoracic trigger points)

Postinjection flare

Skin depigmentation

Subcutaneous atrophy

Tendon rupture

Tenosynovitis

#### Systemic Complications

Acne

Adrenal suppression

Allergic reactions or anaphylaxis from local or preservatives

in multidose vials

Avascular necrosis

Flushing of the face

Impaired glucose tolerance

Menstrual irregularity; uterine bleeding

Muscle wasting and myopathy

Osteoporosis

Pancreatitis

Posterior subcapsular cataracts

Psychological upset

Steroid arthropathy

Syncope

## KNEE BRACES

Scott A. Paluska

The knee joint is the largest joint in the body, and traumatic, overuse, and degenerative knee injuries are common. Strength, flexibility, and technique modification have traditionally been essential components in the treatment of knee pain. Improved surgical techniques, arthroscopic advances, and smaller incisions have also enhanced therapy for knee disorders over the last few decades. More recently, knee braces have been used in an attempt to prevent or treat several knee conditions.

Knee braces typically fall into one of several broad categories:

- Prophylactic: Braces designed to reduce the occurrence or facilitate the recovery of injury to the knee's medial collateral ligament (MCL) or lateral collateral ligament (LCL).
- Functional: Braces designed to restore normal knee kinematics, minimize tibial rotation, and reduce translation for anterior cruciate ligament (ACL)—deficient or ACL-reconstructed knees.
- Patellofemoral: Braces designed to keep the patella centered in the femoral trochlea and improve patellofemoral joint alignment.
- Postoperative: Braces designed to immobilize the knee or limit motion after surgery or an injury.
- Osteoarthritics: Braces designed to diminish painful forces exerted on an affected knee's tibial-femoral compartment (medial or lateral) for unicompartmental knee osteoarthritis.

Despite their popularity, the appropriate indications and true benefits of many knee braces have not been clearly defined or validated by rigorous research. In addition, brace manufacturers market several different knee braces to address conditions that may be nonspecific and diverse. As a result, confusion often exists regarding when and if knee braces should be used for the prevention or treatment of various knee abnormalities. At this point, it can be said that some knee braces may minimize knee injuries, but the efficacy of most braces has not been confirmed by well-controlled studies. In general, most individuals using knee braces express subjective symptomatic improvements that exceed objective findings. Clinicians must assess the costs and potential risks of knee braces when deciding to use them for individuals. Although knee braces appear relatively safe when used appropriately, they should be used only in conjunction with appropriate education, muscular rehabilitation, technique enhancement, and activity modification.

#### **INDICATIONS**

#### **Prophylactic Knee Braces**

- MCL or LCL injury protection during significant valgus or varus knee forces
- MCL or LCL stabilization during recovery following an MCL or LCL sprain
- Athletes or individuals at high risk for MCL or LCL injuries

## **Functional Knee Braces**

- Mild-to-moderate ACL instability
- · ACL-deficient knees treated nonsurgically
- Postoperative support following ACL reconstruction
- Support for mild-to-moderate posterior cruciate ligament (PCL) or MCL instability

#### Patellofemoral Knee Braces

- Patellar subluxation or dislocation
- Anterior knee pain syndromes
- Patellar tendonitis
- Osgood-Schlatter disease
- Compression of a knee effusion

#### **Postoperative Knee Braces**

- Stabilization following an acute knee injury or ligament sprain
- Postoperative immobilization
- Customized range-of-motion limitations for various knee conditions
- Stabilization following a femoral or tibial fracture
- Graft protection following knee ligament reconstruction

#### Osteoarthritis Knee Braces

- Unicompartmental, symptomatic tibial-femoral knee osteoar-thritis
- Neutral or varus knee alignment (for a valgus-force brace)
- Neutral or valgus alignment (for a varus-force brace)

#### **CONTRAINDICATIONS**

#### In General

- Unstable knees requiring prompt surgical management
- Body contours that preclude effective brace positioning
- Regional compartment syndrome that may be exacerbated by brace tension
- Open wounds, cellulitis, or lacerations that will be occluded by the brace

#### **Prophylactic Knee Braces**

Prophylactic knee braces should not be used for control of tibial translation or rotation in ACL-deficient knees.

#### **Functional Knee Braces**

Functional knee braces should not be used for complex knee injuries, such as posterolateral corner injuries.

#### **Patellofemoral Knee Braces**

- Knee disorders unrelated to the patellofemoral joint
- Moderate-to-severe patellofemoral osteoarthritis

#### Osteoarthritis Knee Braces

- Multicompartmental knee osteoarthritis
- Moderate-to-severe patellofemoral osteoarthritis
- Knee arthritis related to other conditions such as inflammatory, infectious, or autoimmune

#### **EQUIPMENT AND SUPPLIES**

#### In General

- Tape measure
- Athletic tape (optional)
- Skin razor (optional)
- Prewrap on skin under brace to limit brace migration (optional, not beneficial for patellofemoral braces)
- Elastic wrap or brace cover (optional)

## **Prophylactic Knee Braces**

- Custom or off-the-shelf (prefabricated) brace with unilateral or bilateral bars
- In addition to athletic tape, there may be manufacturer-supplied hook-and-pile fasteners

#### **Functional Knee Braces**

- Custom or off-the-shelf (prefabricated) brace
- In place of tape measure, there may be specific measuring device supplied by the brace manufacturer

#### **Patellofemoral Knee Braces**

- Custom or off-the-shelf (prefabricated) brace
- Counterbalancing straps (optional)
- Patellar buttresses (optional)
- Inflation device for inflatable air pocket (optional)

#### **Postoperative Knee Braces**

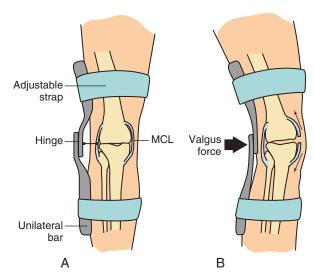

An off-the-shelf (prefabricated) universal-sized brace is used postoperatively.

#### Osteoarthritis Knee Braces

A custom or off-the-shelf (prefabricated) brace is used in cases of osteoarthritis.

## PREPROCEDURE PATIENT EDUCATION

The clinician should identify the appropriate indication for using a knee brace and explain that the brace may or may not be helpful for a given individual. An appropriately sized prefabricated brace is generally sufficient for most individuals. Although custom braces may distribute weight and fit better and be made of materials more worthwhile for high-level athletes or individuals with abnormal limb contours, they are more expensive. If the individual is a minor, consent should be obtained from the parent or guardian. (See the sample patient consent form online at www.expertconsult.com.) The initial fitting and brace application should be scheduled with adequate time allowed for correct sizing and an explanation of recommended brace care and usage. (See the sample patient education form online at www.expertconsult.com.)

**Figure 193-1** Representative prophylactic knee brace. **A,** Unilateral hinged bar prophylactic knee brace in a neutral position. **B,** Valgus-applied force causing increased medial collateral ligament (MCL) tension and potential ligament rupture. Use of the brace would hopefully prevent the MCL tear seen here.

#### **PROCEDURE**

## **Prophylactic Knee Braces**

Prophylactic knee braces are used to prevent injury to the MCL or LCL during contact sports or to provide stability during recovery after an MCL or LCL sprain (Fig. 193-1). Although the routine use prophylactic knee braces for collateral ligament injury prevention may be controversial, they do have a more well-defined role during MCL or LCL rehabilitation. Prophylactic knee braces are available as custom or off-the-shelf (prefabricated) models (Figs. 193-2 and 193-3). They have either a single lateral hinged support or bilateral supports with polycentric hinges that are connected by fabric and closures. Cost is greater for custom models, which appear to have greater efficacy during both knee flexion and extension. Although

**Figure 193-2** Representative prophylactic knee brace with bilateral hinged bars seen from the front.

**Figure 193-3** Representative prophylactic knee brace with bilateral hinged bars seen from the side.

high-level athletes may profit from the weight distribution and fit characteristics of a custom brace, a prefabricated brace is sufficient for most individuals. At-risk athletes, such as football linemen, may particularly benefit from wearing well-fitting prophylactic knee braces on both knees during practices and games. However, it should be noted that prophylactic knee brace use may have a negative impact on an athlete's speed, agility, fatigability, and endurance.

- 1. Obtain the longest brace that the individual can wear comfortably (≥50 cm).
- Select a brace with either unilateral or bilateral bars based on personal preference and cost. Bilateral bars may improve the brace's ability to transfer loads placed on the knee joint during impact.
- Shave the skin under the brace, if desired, to maximize braceto-skin contact.
- Secure and adjust the athletic tape or brace enclosures to minimize brace movement.
- 5. Align the hinge(s) with the femoral condyles to minimize knee range-of-motion attenuation. Correct hinge placement relative to the knee joint is critical for optimal brace efficacy. The side bars may be bent if needed to accommodate the limb contours.
- 6. Cover the brace with the elastic wrap or brace cover, if desired, to minimize brace deterioration or injury to others during activities.
- 7. Tighten and adjust the brace regularly during prolonged athletic activities. It is common for the brace to migrate distally.
- 8. Hand wash and thoroughly dry the brace occasionally to prolong its life and reduce skin irritation.
- 9. Inspect the brace regularly for signs of deterioration or excessive wear
- Periodically apply a dry lubricant, such as Teflon spray, to the hinges.
- 11. Replace a broken or damaged brace.

## **Functional Knee Braces**

The ACL is one of the knee's most important stabilizers for anterolateral motion, and an ACL tear can cause significant knee dysfunction. Functional braces are designed to limit instability in ACL-deficient knees or to stabilize the surgical graft for ACL-reconstructed knees. They are often antirotational. The braces may also enhance proprioception and muscle-timing during activity.

Figure 193-4 Representative functional knee brace seen from the front.

Even though most individuals report subjective improvements with brace wear, the braces' ability to limit knee laxity during high-load, in vivo conditions is clearly less than what has been observed in laboratory models. Theoretically, functional braces may also provide protection for the ACL graft by limiting strain during the initial surgical recovery period. However, functional bracing has not been definitively shown in long-term studies to improve subjective or objective outcomes after ACL reconstruction. As such, functional bracing may be superfluous following uncomplicated ACL surgery.

Functional knee braces are available as custom or off-the-shelf (prefabricated) models (Figs. 193-4 and 193-5). They have similar designs and use either a "hinge-post-shell" or a "hinge-post-strap" design, which differ in the method of securing the brace around the user's thigh and calf. The "hinge-post-shell" braces provide better long-term durability and enhanced soft tissue contact. It is unclear whether the small mechanical and limb-contact advantages demonstrated in the laboratory for the more expensive custom models have clinically meaningful implications versus the less expensive off-the-shelf (prefabricated) knee braces. Custom braces may be more appropriate for individuals participating in high-level activities or

Figure 193-5 Representative functional knee brace seen from the side.

having abnormal limb contours. Prefabricated braces are usually sufficient for most individuals. It is more important that the brace be secured snugly and aligned correctly on the affected leg in order to maximize its efficacy.

- Measure the thigh circumference 6 inches above the midpatella if using a prefabricated brace and select the corresponding brace size according to the manufacturer's instructions.
- Measure the thigh, knee, and calf dimensions with the manufacturer-specific instrument for custom braces. The submitted measurements will be used to fabricate a brace that closely meets the affected individual's leg.
- 3. Choose the longest length brace that the individual can comfortably wear, generally mid-thigh to mid-calf. Longer braces may be more uncomfortable, so balanced brace length and comfort is important to improve compliance.
- 4. Set the bilateral hinge extension stops at 10 to 20 degrees of flexion to minimize potentially harmful knee hyperextension.
- 5 Center the condylar hinge pads over the medial and lateral joint lines to allow the brace's flexion axis to conform to the knee joint.
- 6. Fasten the brace securely around the individual's leg using the brace closures or straps.
- Cover the brace with the elastic wrap or brace cover, if desired, to minimize brace deterioration or injury to others during activities.
- 8. Tighten and adjust the brace regularly during prolonged athletic activities. It is common for the brace to migrate distally.
- 9. Hand wash and thoroughly dry the brace occasionally to prolong its life and reduce skin irritation.
- Inspect the brace regularly for signs of deterioration or excessive wear.
- 11. Periodically apply a dry lubricant, such as Teflon spray, to the hinges.
- 12. Replace a broken or damaged brace.

#### **Patellofemoral Knee Braces**

Patellofemoral knee braces are designed to treat a variety of highly prevalent anterior knee symptoms that occur during activities such as ascending or descending stairs, prolonged sitting, or frequent squatting. Although their mechanism of action is uncertain, patellofemoral braces may diminish pain via improved patellar tracking, lessened lateral patellar tilt, augmented sensory feedback, reduced patellofemoral joint stress, and enhanced joint contact between the undersurface of the patella and the femoral trochlea. Generally, the subjectively reported benefits exceed the objectively measured findings for patellofemoral knee braces.

Patellofemoral knee braces are available in many different styles, but most use an elastic sleeve, a patellar cut-out, and padding around the patella (Figs. 193-6 and 193-7). Some braces also include adjustable straps or moveable buttresses. Most individuals can use a prefabricated brace without the need for customization. No patellofemoral brace type or materials appear to be superior.

- 1. Measure the extended and relaxed leg circumference 6 inches above and 6 inches below the knee joint line or around the mid-patella, depending on the manufacturer's instructions.
- 2. Obtain the corresponding brace size.
- 3. Pull the brace onto the individual's leg and center the patellar cut-out over the anterior knee.
- Align the hinges, if present, with the medial and lateral femoral condyles.
- 5. Position the patellar buttress, if moveable, medial to the patella to apply laterally directed force (uncommon) or lateral to the patella to apply medially directed force (common).
- Snugly secure the counterbalancing straps, if present, around the individual's thigh and calf. Moveable straps should be placed proximally to the patella for most individuals, except for

**Figure 193-6** Representative patellofemoral knee brace seen from the front.

- those with patellar tendonitis who may benefit from a more distal placement.
- 7. Apply athletic tape to the top and bottom of the brace, if desired, to minimize brace migration during activities.
- 8. Hand wash and thoroughly dry the brace occasionally to prolong its life and reduce skin irritation.
- Inspect the brace regularly for signs of deterioration or excessive wear.
- 10. Replace a broken or damaged brace.

#### **Postoperative Knee Braces**

Postoperative knee braces are designed to provide immobilization and protected range of motion following a knee ligament injury, fracture, or surgical procedure. The braces may be used to keep the knee fully extended or limited within any desired range of motion. During the course of treatment or recovery, the allowable motion is typically advanced gradually. Postoperative knee braces are not designed to be worn during athletic endeavors but may be used during full or partial weight-bearing ambulation.

Figure 193-7 Representative patellofemoral knee brace seen from the side.

**Figure 193-8** Representative postoperative knee brace seen from the front.

Postoperative knee braces are primarily prefabricated and universally sized (Figs. 193-8 and 193-9). Some individuals with abnormal limb contours may need a custom brace. It is essential that the brace be correctly positioned and securely attached on the affected leg in order to stabilize the knee adequately.

- 1. Unfasten all of the buckles and loosen the strap enclosures.
- 2. Pull the brace onto the individual's leg and center the patellar cut-out over the anterior knee.
- Wrap the foam thigh and calf inserts securely around the leg and attach the free ends together. The foam may be trimmed if necessary.

**Figure 193-9** Representative postoperative knee brace seen from the side.

- 4. Adjust the brace length by pressing the medial and lateral release buttons, allowing the side bars to telescope to the desired length. If necessary, the bars may be fully extended from the upper thigh to the ankle. After finishing the adjustments, confirm that the release buttons have reengaged and that the side bars are equivalent in length.
- 5. Align the hinges with the patella and midline (anterior/posterior plane) of the affected leg. The lateral malleolus and greater trochanter may be used to verify midline placement. The hinge bars may be bent to fit varus or valgus knee alignments.
- 6. Confirm that the medial and lateral hinge heights are the same. Correct hinge placement is important for brace efficacy.
- 7. Adjust the brace's strap lengths and snap the buckles closed, starting with those closest to the patella.
- 8. Open the bilateral hinge covers and set the desired limitations of flexion and extension by moving the adjustment pins.
- 9. Tighten and adjust the brace regularly during prolonged wear. It is common for the brace to loosen slightly or migrate distally.
- 10. Hand wash and thoroughly dry the brace to prolong its life and reduce skin irritation.
- Inspect the brace regularly for signs of deterioration or excessive wear.
- 12. Periodically apply a dry lubricant, such as Teflon spray, to the hinges.
- 13. Replace a broken or damaged brace.

#### Osteoarthritis Knee Braces

Knee osteoarthritis is a widespread disorder, and osteoarthritis knee braces have gained prominence as nonsurgical adjuncts in the treatment of unicompartmental degenerative changes. Many studies have confirmed the braces' subjective and objective benefits among symptomatic individuals. Osteoarthritis knee braces (Figs. 193-10 and 193-11) play an important role in addition to standard treatments of pharmacotherapy, intra-articular injections, heel wedges, regional muscle strengthening, and lifestyle modifications. The brace applies three-point forces periarticularly to reduce load on one side of the tibial-femoral knee joint. A varus (force is laterally directed) knee brace provides distracting pressure on the knee to

**Figure 193-10** Representative osteoarthritis knee brace seen from the front.

**Figure 193-11** Representative osteoarthritis knee brace seen from the side.

off-load symptomatic lateral tibial-femoral osteoarthritis, and a valgus (force is medially directed) knee brace provides distracting pressure on the knee to off-load symptomatic medial tibial-femoral degenerative changes.

Most individuals can use a prefabricated brace without the need for more expensive customized osteoarthritis knee braces. No brace type or materials have been shown to be superior for improving pain or function. Obese individuals or those with abnormal limb contours typically have less success with the use of osteoarthritis knee braces. Moreover, some individuals are unable to tolerate the forces created by osteoarthritis knee braces very well during daily activities.

- Measure the thigh circumference 6 inches above the midpatella and select the corresponding brace size according to the manufacturer's instructions.
- 2. Some braces may also require measuring the calf circumference 6 inches below the mid-patella or the circumference of the knee at the joint line.
- Loosely apply the brace to the leg without tightening the closure straps while the patient stands.
- 4. Adjust the varus and valgus alignment to fit the contours of the individual's leg. The side bars may be bent if needed.
- 5. Have the individual sit and flex the knee to 45 degrees. Position the side hinges 1 inch above the patella with the brace centered on the midline of the leg.
- 6. Secure the lower calf and the upper thigh straps snugly.
- 7. While the knee is still bent at 45 degrees, push both condylar hinges posteriorly to the midline of the leg. Hold the hinges in this position while securing the lower thigh strap.
- 8. While the knee is still bent at 45 degrees, pull both condylar hinges slightly forward but not anteriorly to the midline of the leg. Hold the hinges in place while securing the upper calf strap.
- 9. Confirm that both side hinges are centered just above the patella and slightly posterior to the leg's midline.
- Tighten and adjust the straps after a few steps and then regularly during prolonged athletic activities. It is common for the brace to migrate distally or loosen slightly.
- 11. Trim the pads and straps as needed for comfort or to accommodate limb contours.
- 12. Cover the brace with the elastic wrap or a cover, if desired, to minimize brace deterioration or injury to others during activities.
- 13. Periodically apply a dry lubricant, such as Teflon spray, to the hinges.

- 14. Hand wash and thoroughly dry the brace occasionally to prolong its life and reduce skin irritation.
- Inspect the brace regularly for signs of deterioration or excessive wear.
- 16. Periodically inspect and tighten the hinge screws as needed.
- 17. Replace a broken or damaged brace.

#### **COMMON ERRORS AND COMPLICATIONS**

In general, knee braces are associated with few complications when selected and worn appropriately. Careful brace sizing and maintenance may limit unwanted side effects. However, the following may occur:

- Skin breakdown or irritation may occur from brace-to-skin contact over bony prominences. Regularly cleaning and air drying the brace may also help protect the skin's integrity.
- Athletes or highly active individuals may note diminished endurance, performance, speed, and range of motion.
- Brace wear may require increased energy expenditure during vigorous activities.
- Premature muscle fatigue resulting from regional muscle ischemia and lactic acid accumulation may limit activities.
- While wearing a knee brace, an individual may harbor a false sense of security or invincibility regarding the brace's efficacy and subsequently sustain a more significant knee injury.
- Some knee braces may interfere with an individual's knee proprioception.
- Brace-related contact injuries to others may occur.
- Excessive preloading of the knee ligaments by some braces may potentiate the severity of a knee injury.
- Some braces may cause symptomatic regional ipsilateral or contralateral lower extremity discomfort due to altered knee kinematics and gait.

#### POSTPROCEDURE PATIENT EDUCATION

Give the individual a copy of any materials provided by the brace manufacturer. It is also important to remind him or her of the following:

- Routinely inspect the brace for any signs of wear or deterioration.
   It is common for braces that are used for extended periods of time to need new pads, foam inserts, or enclosure straps.
- Knee braces are only one part of a comprehensive knee rehabilitation program. More important components of knee injury prevention and treatment include muscular strengthening, flexibility enhancement, and technique modification.
- The patient should report any of the following in regard to the knee brace: poor fit, mechanical dysfunction, skin breakdown or irritation, new-onset knee pain, or concerns regarding proper brace usage.

# Nursemaid's Elbow: Radial Head Subluxation

Russell D. White • Christopher F. Adams

Nursemaid's elbow (radial head subluxation [RHS]) or "pulled elbow" is a common injury to children under 7 years old. The mechanism of injury is usually sudden axial traction of the outstretched, pronated forearm. It often occurs when a parent picks the child up and suspends the child's entire weight while holding only their hands. Alternatively, the child may have asked to be "swung around" while holding their hands. At times, the injury occurs unobserved by an adult. Regardless of mechanism, the child initially complains of pain and then refuses to use the arm. The concerned parents then take the child to seek medical attention.

The elbow consists of the articulation of the humerus, ulna, and radial head. The radius and ulna flex and extend against the humerus; the radial head can also rotate against the ulna and capitellum (humerus) to permit forearm pronation and supination. The radial head is held in place against the proximal ulna and capitellum by the annular ligament and joint capsule. In infants and young children, sudden traction on the distal forearm is sometimes more than the annular ligament can sustain; consequently, the radial head slides distally and partially dislocates or "subluxes." Presumably the annular ligament or synovial tissue becomes interposed between the radial head and capitellum, causing discomfort and preventing the radial head from spontaneous reduction.

#### **DIAGNOSIS**

Often the history suggests the diagnosis. Typical scenarios for radial head subluxation include a caregiver pulling a child out of harm's way, a reluctant child being pulled along by the hand, a child suddenly dropping to the floor while being held, or a child being swung playfully by the arms. It is not uncommon for the subluxion to occur unwitnessed; in that case, the child may provide the history of having fallen or rolled over in bed. At presentation, the child expresses acute pain, refuses to move the affected extremity, and holds the elbow in a pronated and slightly flexed position (the nursemaid's position). Examination reveals no deformity and little if any swelling around the elbow. (Having the parent question the child and examine for areas of tenderness, with the clinician's guidance, may be less threatening than examination by the unknown clinician.) The child resists range of motion at the elbow, including further flexion or extension as well as supination and further pronation.

Some tenderness is noted over the radial head, but not the supracondylar regions. Neurovascular compromise is rare with this injury. Not infrequently, a child will have no known traction injury but holds the arm against the chest, refuses to use the arm, and has no significant deformity, swelling, or neurovascular compromise. The absence of a classic history of axial traction does not rule out the diagnosis of radial head subluxation. A small retrospective study found that a third of the 45 cases of nursemaid's elbow in the emergency department did not have a history of axial traction.

#### **RADIOGRAPHIC STUDIES**

The clinician should take standard elbow radiographs, including three views (anteroposterior, lateral, and oblique). Comparison radiographs of the contralateral elbow are essential in the young child because incomplete ossification increases the difficulty in evaluating the immature elbow structures and alignment. Radiographs of nursemaid's elbow are usually normal or reveal longitudinal misalignment of the radial head with the capitellum. The subluxation is occasionally reduced by the technician when taking the radiographs; the child is often distracted while being positioned for three radiographs and this may allow the elbow to be supinated and flexed. The child then returns to the clinical area using the affected extremity.

The clinician should evaluate the radiographs for the presence of a "fat pad sign" (joint effusion), location and alignment of epiphyseal growth centers, and the longitudinal alignment of the radial head with the capitellum. The fat pad sign is positive if a radiolucent stripe is visible at the posterior distal aspect of the humerus on the lateral view of the elbow and not visible on the comparison view. The periarticular fat is displaced posteriorly by an increase in intra-articular joint fluid, making it visible in the lateral view. This is a nonspecific finding. A positive fat pad sign associated with a history of trauma suggests a bloody joint effusion and intra-articular injury. In this case immediate orthopedic referral is recommended. A nurse-maid's elbow can still be present despite the absence of a fat pad sign; in fact, that is generally the rule.

Misalignment of the ossification centers suggests a growth plate injury. Orthopedic referral is recommended for growth plate injury or other obvious fracture. Elbow fractures have a high complication rate.

We would never recommend manipulation of the patient, even with classic symptoms, before a radiographic study has been performed, although some clinicians do.

#### **INDICATIONS**

A child holding his or her arm in a pronated, partially flexed position, refusing to use it, often with a history of axial traction compatible with radial head subluxation (but not always), and negative radiographs indicates nursemaid's elbow.

#### **CONTRAINDICATIONS**

- Edema or ecchymoses over the site
- Fracture (or suspicion of a fracture if no radiographs obtained)
- Mechanism of injury inconsistent with radial head subluxation (unless radiographs negative)
- Presence of distal neurologic or vascular compromise (orthopedic consultation recommended)

#### PREPROCEDURE PATIENT EDUCATION

The procedure, as well as any risks and alternatives, should be explained to the patient and caregivers. Informed consent should be obtained. The patient can be sitting or supine on an examination table or sitting in a parent's lap. No preprocedure medications are generally required.

## **TECHNIQUE**

Supination and flexion of the forearm has been the usual method described in modern literature, including the first edition of this text, to reduce RHS. More recently, a method of hyperpronation with flexion has been evaluated as a safe and effective alternative technique for reduction of RHS, and has been shown in small studies to be a less painful method of reduction. The techniques differ in the direction the forearm is rotated.

## **Supination and Flexion Method**

Figure 194-1 illustrates the supination and flexion method.

- The elbow is held in one of the operator's hands (usually the nondominant hand) with either the thumb or second and third fingers exerting constant gentle pressure over the radial head in a medial direction.
- 2. While applying slight distal traction with the operator's other hand, the patient's wrist is supinated.
- 3. The patient's forearm is then rapidly raised toward the upper arm, flexing the elbow past 90 degrees. This should all be done in one smooth motion, and a click may be felt by the finger held over the radial head as it is reduced.
- The forearm is moved so that the elbow is in 90 degrees of flexion and released.
- The success of the manipulation is often tested by offering the child his or her favorite toy or a piece of candy on the side of the affected arm. If the child reaches with the affected arm, the manipulation was successful.
- The child should be using the forearm normally within 30 minutes or else a repeat manipulation can be attempted. Using the alternative method of hyperpronating the forearm and rapid flexion has been successful even when repeat supination and flexion has failed.

**Figure 194-1** The reduction maneuver for a subluxed radial head (nursemaid's elbow) involves gentle supination of the forearm and flexion of the elbow. The examiner's thumb can be placed over the child's elbow to help palpate the radial head during the reduction process.

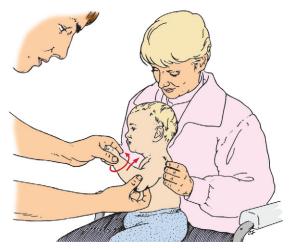

Figure 194-2 Pronation and flexion method.

# Pronation and Flexion Method (Hyperpronation)

Figure 194-2 illustrates the pronation and flexion method.

- The elbow is held with one of the operator's hands with the thumb or second and third fingers again exerting constant gentle medial pressure on the radial head.
- 2. While the operator applies slight distal traction, the patient's wrist is hyperpronated with the operator's other hand.
- 3. Rapid flexion at the elbow is performed; this should all be done in one smooth motion.
- 4. The elbow is extended to 90 degrees and released.
- 5. The success of manipulation is tested as noted previously.

Sometimes a click, snap, or satisfying clunk of the radial head may be felt, indicating reduction. Spontaneous reduction without manipulation may also occur before evaluation by the clinician. The caregivers generally need assurance that the child has suffered nothing serious.

#### **DIFFERENTIAL DIAGNOSIS**

If there is concern regarding the possibility of a growth plate injury, generally the best approach is to obtain an orthopedic consultation. Rarely, an arthrogram is needed to determine the extent of injury. Sedation or general anesthesia is often required to complete that study. The radiographic contrast material can help to outline articular surfaces and to give the examiner a better understanding of the nonossified anatomy.

Alternative diagnoses include osteomyelitis or clavicular, distal humeral, stress, or radial head fracture. Joint aspiration can be performed if there is concern regarding the possibility of more significant trauma or infection in the elbow (see Chapter 192, Joint and Soft Tissue Aspiration and Injection [Arthrocentesis]). Bloody fluid confirms the presence of a traumatic intracapsular injury, such as a fracture. Purulent material confirms the diagnosis of septic arthritis. Routine elbow aspiration is not recommended for a nursemaid's elbow; it is merely an adjunctive procedure that can be used in difficult diagnostic situations. Sedation or general anesthesia may be required. If any of the preceding diagnoses are being considered, an orthopedic surgeon should be consulted.

#### POSTPROCEDURE PATIENT EDUCATION

After successful reduction of a subluxed radial head, the provider should tell the child to rest the limb for several days and then reevaluate the child with follow-up clinical and possibly radiographic examination if symptoms do not totally resolve in 24 to 48 hours. If reduction is delayed more than 8 hours from the time of injury, it may take the full 24 to 48 hours to recover. A small percentage of patients will resublux the radial head within a few days of reduction, although the number and risk factors are not well defined. In a small randomized prospective study, immobilization in a flexed, supinated position with a posterior splint reduced the recurrence rate from 13% to zero (p < .05) at follow-up 2 days after manipulation (Taha, 2000). Children who remain reluctant to use their elbow in a normal fashion should be splinted from shoulder to hand. Follow-up evaluation in 2 or 3 days is recommended to determine normal joint function. If not normal at that point, orthopedic referral should be considered. Patients with splints should not remove the splint until the short-term follow-up examination.

Generally, children will let their symptoms be their guide in regard to activity level; once they are comfortable, they will resume their activities. It may take several days for them to do so. The long-term prognosis of nursemaid's elbow is generally favorable. Occasionally the child will have several episodes of subluxation, but the incidence drops off significantly after age 7. Caregivers should be educated regarding the mechanism of injury and how to avoid future subluxations. Long-term functional or growth problems are rare after appropriate treatment of this injury. Congenital radial head dislocation is a separate entity and is not related to the common pediatric problem of nursemaid's elbow.

## **CPT/BILLING CODES**

24640 Closed treatment of radial head subluxation in child, nursemaid elbow, with manipulation

29105 Splint, arm, long (shoulder to hand)

## PODIATRIC PROCEDURES

Gary L. Snyder • Grant C. Fowler

#### **ORTHOTICS**

Orthotics are prescribed, in-shoe devices designed to protect and improve abnormal foot function. Orthotics are custom made and, as such, may differ in the materials from which they are manufactured. Each prescription may have various modifications and additions depending on the underlying diagnosis. The two most common types of orthotics are functional orthotics and accommodative orthotics. Both of these are made from precise casts, impressions, or scans of the patient's foot that has been placed in the position in which the practitioner wishes the foot to function. Although symptoms improve with conservative care in the vast majority of patients with plantar fasciitis in 3 to 6 months, no matter what the treatment, Cochrane evidence-based reviews found possible benefit with custom-made orthotics in patients with this disorder. Cochrane reviews also found possible benefit with custom orthotics in patients with painful pes cavus (high-arching foot), painful hallux valgus (bunion), rearfoot pain due to rheumatoid arthritis, and foot pain due to juvenile idiopathic arthritis (patients older than 5 years of age). Other reviews have found that 70% of patients improved with orthotics versus 30% with heel cups or injections. According to one study, after 1 year, most patients prefer custom orthotics to other devices (e.g., night splints) for preventing or managing foot pain.

**EDITOR'S NOTE:** Vendors with digital foot scanning systems have recently become much more common and offer custom orthotics. It should be noted that such orthotics will not be able to provide the frequently needed accommodative pads or customized balance support.

Most (70%) patients are heel strikers, and in these patients about 50% of the stress of weight bearing is borne or transferred through the calcaneus, whereas the other 50% is transferred to the first and fifth metatarsophalangeal (MTP) joints (about 35% to the first MTP). Although malalignment anywhere in the lower extremity can change this weight-bearing pattern, the normal pattern is therefore from the calcaneus, through the midfoot, and then off the first and fifth MTP joints. Orthotics can be useful for patients with abnormalities in their weight-bearing pattern. Corns and calluses may not only develop as a result of weight-bearing abnormalities, but their location may also help diagnose or confirm the abnormality. Exceptions to the normal weight-bearing pattern are patients with a very narrow heel and wide forefoot; they are likely forefoot strikers. Plantar warts, hammer (claw and mallet) toes, bunions, bunionettes, metatarsalgia, sesamoiditis, and hallux rigidus (stiff toe) can all be uncomfortable and have an impact on the weightbearing pattern; significant relief is often provided by a simple podiatric adjustment or procedure.

## **Functional Orthotics**

Functional orthotics are usually rigid or semirigid thermoplastic shells with built-in corrections or additions to change a foot's position or to control abnormal foot motion. Flexible deformities of the foot are most frequently treated with this type of orthotic.

#### **Accommodative Orthotics**

Accommodative orthotics are softer and more cushioned, designed to protect painful plantar lesions or bony deformities of the foot. A number of closed-cell and open-cell foam products—as well as cork, leather, rubber, and silicone—are used in the fabrication of accommodative orthotics. These designs are most frequently used with rigid foot deformities, arthritic foot changes, and certain diabetic conditions. In some cases, they may be useful early in a disease process that will later require surgery.

## Indications (Rigid, Custom Orthotics)

- Plantar fasciitis (with or without heel spur syndrome)
- Pes cavus (Although people with this "high-arching foot" [defined as >3 cm height from ground measured at navicular bone] may never have a problem, they have a sixfold increased risk of injury with sports, largely because of an inflexible foot that does not adjust well to uneven surfaces; they also have a higher risk of plantar fasciitis.)
- Pes planus (flat foot)
- Excessive pronation (Fig. 195-1) resulting in problems (e.g., tibialis posterior dysfunction or medial tibial stress syndrome, metatarsalgia, tarsal tunnel syndrome)

NOTE: Examination may reveal a long, narrow foot, usually resulting in the patient rolling the foot excessively (excessive pronation) with ambulation. Deviations from the normal leg-heel-forefoot alignment may also be noted. Direct observation or videotaping of training routines may also be necessary to diagnose biomechanical abnormalities that are not noticed on routine examination. Pes planus, tibia vara, tibial torsion, subtalar joint varus, and heel cord tightness are possible causes of malalignment.

- Painful corns and calluses (following treatment, to prevent recurrence)
- Hammer toes (flexible)
- Early bunion (hallux valgus) deformity
- Stiff toe (hallux rigidus)
- Morton's neuroma
- Chronic lateral ankle instability

#### **Indications**

## (Soft, Accomodative Custom Orthotics)

- Diabetic foot pathology such as Charcot changes or plantar ulcerations
- Patients with arthritis or arthrosis

## **Contraindications (Relative)**

 Other than allergy to orthotic material, there are usually no contraindications.

**Figure 195-1** Excessive, unchecked pronation demonstrated with weight bearing.

- Care must be taken with the neuropathic (e.g., diabetic) foot to ensure an exact fit.
- Some difficulty exists in fitting prescription orthotics for women's and men's dress shoes, although specialty laboratories do manufacture these devices.
- When anticipating a functional rigid or semirigid orthotic, the patient's range of ankle dorsiflexion must be greater than 10 degrees with the knee extended.

## **Equipment**

More than 100 different prescription orthotic laboratories are accredited throughout the United States. The choice of laboratory is left to the discretion of the practitioner. Langer Biomechanics, Inc. (Deer Park, NY), is an example of an excellent facility and can be a very helpful resource.

Impressions taken in the office can be performed with the following techniques:

- Johnson & Johnson Extra-Fast Setting plaster casting tape (available from Moore Medical Corporation, New Britain, Conn)
- ScanCast Optical Scanner (Fig. 195-2; Benefoot/Langer)
- Biofoam Impression Kit (Smithers Bio-Medical Systems, Kent, Ohio)

#### **Impression Techniques**

#### Plaster Cast Technique

Four-inch-wide Johnson & Johnson Extra-Fast Setting casting splints can be used, usually two layers thick. The casting tape is wrapped around the foot to completely cover the heel, medial and lateral margins, plantar aspect, and toes (Fig. 195-3). The casting tape is then smoothed to ensure full contact with the foot, and the foot is immediately placed in the desired functional position. The procedure is repeated for the other foot. When the casting tape dries, the feet are easily released from these "slipper casts."

**Figure 195-2** ScanCast 3D is a portable, self-contained unit. (Courtesy of Benefoot/Langer Biomechanics, Inc., Deer Park, NY.)

#### ScanCast Technique

Using ScanCast (Benefoot/Langer), the foot is placed in the desired functional position in front of the ScanCast screen (Fig. 195-4). Foot position is confirmed and visualized. The scan function is activated. Scanning takes approximately 1 second and is then repeated for the other foot. A digital image of the plantar surface of each foot is recorded. Orthotics are developed from these scans. (A positive model of each foot is constructed and the orthotic is molded onto this model.)

#### **Biofoam Impression Technique**

With one of the clinician's hands, the patient's ankle should be stabilized and held in a neutral position (preventing pronation) by supporting the talus. The patient's foot is then placed lightly over the foam in the impression kit, and the patient is instructed to avoid applying pressure. For additional stability, the clinician can quickly shift the stabilizing hand to the lateral aspect of the foot. Using the other hand, the clinician applies downward pressure on the patient's knee to make an impression of the foot in the foam. The foot should be pushed 1 to 1½ inches into the foam while simultaneous, stabilizing pressure is applied to the lateral aspect of the foot. Finish the

**Figure 195-3** Casting tape applied to foot. (Courtesy of Benefoot/Langer Biomechanics, Inc., Deer Park, NY.)

**Figure 195-4** Using the ScanCast 3D to scan the foot. (Courtesy of Benefoot/Langer Biomechanics, Inc., Deer Park, NY.)

impression by using both hands to press the toes into the foam. In this manner, weight-bearing flow is simulated, from heel to midfoot to toes. Alternatively, with a good grasp on the lateral aspect of the foot, one hand can be used to both stabilize and push the foot into the foam and make the impression (Fig. 195-5A). Inspect each impression for defects, unevenness of the weight-bearing surface, or abnormal plantar contour (Fig. 195-5B). Repeat the procedure with the patient's other foot.

#### **Foot Position**

There are four basic positions that may be used to obtain a cast of the foot for an orthotic:

- 1. Subtalar neutral position, non-weight bearing
- 2. Subtalar neutral position, partial weight bearing
- 3. Rectus position
- 4. Full weight bearing

**NOTE:** One of the authors (GLS) suspects it is of little consequence which position is used to obtain the cast, scan, or impression as long as the mid-tarsal, subtalar, and ankle joints are in a neutral and "locked" position. His preference is to use the non–weight-bearing position for fitting custom orthotics and he reserves a weight-bearing position for obtaining certain radiographs.

#### Subtalar Neutral Position, Non-Weight Bearing

This technique is used most frequently and captures the "neutral" position of the foot. The patient may be sitting, supine, or prone with the feet hanging free over the end of the examination table. The ankle is kept at right angles to the leg. This technique can be used for the casting tape (see Fig. 195-3), ScanCast Optical Scanner (see Fig. 195-4), or Biofoam Impression (see Fig. 195-5). First, get

a feel for what is the neutral position of the foot by inverting and everting, pronating and supinating it while palpating the medial and lateral aspects of the head of the talus with the thumb and index finger (at the talonavicular joint) of one hand. Next, stabilize the talonavicular joint in a neutral, congruous position, midway between inversion and eversion, pronation and supination. Then, with the other hand, grasp the foot on the dorsal and plantar aspects of the fifth metatarsal head (at the MTP joint) and maximally pronate the mid-tarsal joint (see Fig. 195-4). (One author [GLS] grasps the great toe and gently pulls down and lateral so that the foot is in approximately 15 degrees of external rotation.) The foot is held in this position until the casting tape dries (see Fig. 195-3) or the scanning is completed, or while a biofoam impression is made.

**NOTE:** Useful when maximum biomechanical control of forefoot and rearfoot deformities is required (e.g., flexible pes planus [flat foot] deformity, tibialis posterior dysfunction or medial tibialis stress syndrome, most pediatric deformities). Best for pes planus with greater than 10 degrees ankle dorsiflexion mobility. Most commonly used with sport orthotics.

#### Subtalar Neutral Position, Partial Weight Bearing

With this technique, the patient sits comfortably with the knee flexed at 90 degrees, the ankle at 90 degrees, and the center of the patella located directly over the second MTP joint. The foot is placed in the neutral position (Fig. 195-6), the position of function, and is then either wrapped in casting tape or placed over the Biofoam Impression Kit and carefully pressed into the foam (see Fig. 195-5). If casting tape is used, the patient is placed on a 2-inch-thick, plastic-wrapped foam pad until the casting tape dries. Care is taken to avoid inverting or everting the heel during the impression stage.

**NOTE:** This technique is indicated for most flexible foot deformities (e.g., pes cavus, pes planus, plantar fasciitis, heel spurs, bunions, painful corns, or calluses on the plantar aspect of the foot).

#### **Rectus Position**

This technique is similar to the non-weight-bearing neutral position, except that the forefoot is held parallel to the plantar aspect of the rearfoot during the time the plaster is drying or the foot is being scanned.

**NOTE:** This technique is indicated for childhood foot deformities (e.g., metatarsus adductus, pes cavus, pes planus, and calcaneal valgus).

#### **Full Weight Bearing**

The practitioner can choose plaster or a scanning system similar to the ScanCast Optical Scanner. The patient is instructed to stand in a normal angle and base-of-gait (with the foot held in the neutral

**Figure 195-5** Taking foam impressions. **A,** Ankle should not be supinated or pronated. **B,** Inspect each impression for defects or unevenness of the weight-bearing surface, or abnormal plantar contour. (Courtesy of Smithers Bio-Medical Systems, Kent, Ohio.)

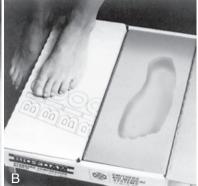

Figure 195-6 Partial weight-bearing, neutral functional position.

position by the clinician while palpating the talonavicular joint; Fig. 195-7) while plaster is drying or the foot is being scanned.

**NOTE:** Full weight-bearing impressions are useful for rigid and arthritic foot deformities, where accommodative padding under pressure points will be beneficial.

#### **Complications**

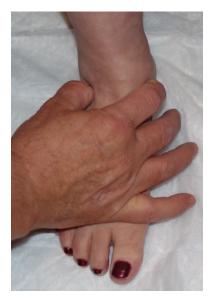

Reported adverse effects include additional foot pain, ankle instability, and skin irritation. Many adjustments can be performed in the office to minimize these or other adverse effects, usually relating to thickness, width, or position of accommodation. Shoe fitting can be difficult with some dress shoes.

#### **Postprocedure Patient Education**

Patients are instructed to initially wear an Oxford-style shoe, at least five eyelets per side, with a removable manufacturer's insole. They begin by wearing the orthotics approximately 1 hour per day; they can then increase the wearing time as tolerated. Average break-in period is between 4 and 12 weeks. If ankle equinus is present, the patient is instructed to continue with gastrocnemius-soleus—stretching exercises. It usually takes 12 weeks to obtain the maximum benefit from orthotics.

# CORNS (HELOMAS, CLAVI), CALLUSES (TYLOMAS), AND PLANTAR KERATOMAS

Corns are discrete, localized, well-circumscribed, round to oval hyperkeratotic lesions found on the toes, usually overlying bony prominences or digital deformities. They are usually painful and can be disabling. Corns involve the dermis and epidermis. Soft corns

**Figure 195-7** Weight-bearing, neutral position, demonstrated by palpating the talonavicular junction.

(heloma molle) are usually interdigital lesions resulting from abnormal pressure from deformed joints, bony prominences, or improperor tight-fitting shoes (Fig. 195-8). Friction or structural deformities cause mechanical irritation between the toes. Soft corns are most commonly found between the fourth and fifth toes on the digital surface, but they can occur in any interdigital space or on the webspace. These lesions often become macerated (by absorbing moisture) and even secondarily infected. After paring or débridement, a small sinus tract can occasionally be identified and can be a source of underlying infection or inflammation. *Hard corns* (heloma durum) are usually found on the dorsum of an interphalangeal joint (second to fourth) or on the dorsolateral aspect of the fifth toe. These lesions result from structural deformities or bony prominences—pressure, shear forces, or friction from footgear over these prominences causes thickening and nucleation of the skin.

Corns are usually uniform in color and vary from whitish-gray to yellowish-gold. Subdermal hemorrhages can cause areas of discoloration that may appear dark red, brown, or black. Lesions are painful to direct and indirect pressure over the area. When débrided or pared down, a central, translucent, pearl-white core is usually found over the area of greatest pressure. Corns can be distinguished from warts by the lack of thrombosed tiny blood vessels on examination as well as the lack of punctate bleeding when débrided. Skin lines pass through corns but around warts (Box 195-1). These skin lines are often more apparent after alcohol is used to cleanse the area.

**Figure 195-8 Soft corn on lateral aspect of the toe.** (Courtesy of John L. Pfenninger, MD, The Medical Procedures Center, PC, Midland, Mich.)

## Box 195-1. Distinguishing Features of Warts and Plantar Corns

#### Wart

- Relatively rapid onset
- May or may not be under bony prominences
- Skin lines pass around lesion
- Maximum pain on squeezing side to side
- End arteries visible as red or black dots on paring
- Rapid recurrence after shaving and padding

#### Plantar Corn

- Develops over months or years
- Located under bony prominences
- Skin lines pass through lesion
- Maximum pain with direct pressure
- No end arteries visible on paring
- Slower recurrence after shaving

From Singh D, Bentley G, Trevino SG: Callosities, corns, and calluses. BMJ 312:1403–1406, 1996.

Calluses are broad-based, poorly circumscribed, hyperkeratotic lesions commonly found on the plantar aspect of the foot at sites of friction or high pressure. They may be quite painful when located under the MTP joints. Calluses by definition involve primarily the epidermis and can occur diffusely around the heel or on the margins of the toes. Because most (70%) patients are heel strikers, and it is then normal to transfer weight through the midfoot and off the great (first) and fifth MTPs, calluses are common on the heels and under the first, second, and fifth MTP joints. (Calluses located between these areas often indicate abnormal foot structure or function.) A callus, differing from a corn, usually does not have a "nucleus" and instead consists of diffuse hyperkeratotic tissue (Fig. 195-9). The intractable plantar keratoma (Fig. 195-10) is a unique lesion consisting of an overlying callus with significant epidermal, dermal, and subdermal alterations, including fibrosis of the surrounding tissue. These are deep, nucleated plantar calluses found beneath an MTP joint and are often extremely painful with palpation and ambulation. They are usually circular, of smaller diameter than a tyloma, and exhibit a central "plug" or fibrous core on scalpel débridement. Intractable plantar keratomas are strong indicators of forefoot or rearfoot joint instability and therefore often benefit from rebalancing the weight-bearing surface with orthotics.

**Figure 195-9** Callus on foot. The differential includes a plantar wart. (Courtesy of John L. Pfenninger, MD, The Medical Procedures Center, PC, Midland, Mich.)

**Figure 195-10** Intractable plantar keratoma showing solid, smooth, hard central core. There are no pinpoint bleeders characteristic of a wart. (Courtesy of John L. Pfenninger, MD, The Medical Procedures Center, PC, Midland, Mich.)

## **Etiology**

Corns and calluses consist of multiple layers of flat sheets of  $\alpha$ -keratin ( $\beta$ -keratin is found in reptile and fish scales), which has an underlying protein matrix consisting mostly of the amino acid cystine. Cystine, in turn, is formed by linking multiple molecules of the amino acid cysteine with disulfide bonds (Fig. 195-11). Clinicians are often familiar with the pungent sulfur odor released by these disulfide bonds when hair, skin, or a fingernail is cauterized or burned. Corns and calluses generally occur as a result of abnormally high pressure from a deformity, footgear, shear forces, or friction from ambulation. They can also be the result of permanently plantar flexed or hypermobile metatarsals as well as instability of the joints of the forefoot and rearfoot. Figure 195-12A shows normal metatarsal alignment; Figures 195-12B and C show how to test for permanently inflexible joints or hypermobile joints by moving the second and third metatarsal heads through their full range of motion.

#### **Differential Diagnosis**

- Verrucae
- Digital bursa
- Dermal and epidermal malignancies
- Porokeratosis plantaris discreta (caused by keratin-plugged sweat duct)

## **Techniques**

Treatment should not only provide symptomatic relief, but attempt to lessen or alleviate the underlying biomechanical cause(s) inciting the problem. Use of shoes with a wider toe box or thicker socks may remove some of the pressure (see Postprocedure Patient Education for how to fit a shoe correctly using the Brannock device). Wearing a thin layer of cotton socks under a thicker layer of socks may reduce friction or shear forces on skin. Correcting or minimizing deformities with orthotics may prevent recurrence. Attempts should be made to correct bony angulation or flexibility defects with padding or orthotics, to see if they are beneficial, before performing corrective surgery.

**Figure 195-11** Two molecules of cysteine are linked by disulfide bonds to form cystine, a major component of the underlying matrix in human keratin.

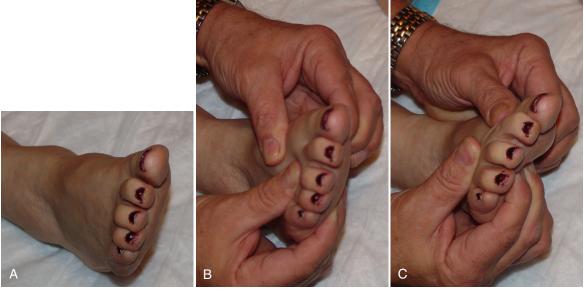

Figure 195-12 A, Normal metatarsal alignment. B, Testing metatarsal head flexibility with excessive pronation. C, Testing metatarsal head flexibility by hyperflexion.

#### Débridement

Débridement should be considered for hyperkeratotic lesions causing symptoms or showing signs of extreme dryness or intralesional cracking and fissuring. In the office, most clinicians use a no. 10 or no. 15 scalpel blade on a handle to remove hyperkeratotic tissue from corns or calluses. The scalpel is held parallel to the lesion and, using small, straight, or circular motions, the lesion is gradually shaved, débrided, or pared back. A thin layer is removed with each pass of the instrument. Because hyperkeratotic skin is devoid of innervation (has no sensation), the patient is usually able to tolerate débridement without a local anesthetic. To minimize discomfort, avoid placing pressure downward into the lesion; instead, pressure should be directed across the lesion with the scalpel. When most of the lesion has been removed, the clinician can usually visualize pink, viable skin just beneath it. This pink tissue has sensation, and as the clinician gets closer to shaving through it, the patient will usually sense or complain of some discomfort. This tissue also has a viable blood supply. In fact, the patient can guide and warn the clinician: as the sensation increases, the majority of the hyperkeratotic skin has been débrided and this is the point where bleeding is likely to start.

Débridement can also be accomplished with various razor blade-containing devices, a pumice stone, electric drill, or keratolytic agents such as weak salicylic acid plasters. It is easier to use a pumice stone if the area has been soaked and softened. Of course, débridement is only a temporary cure, and the lesion will recur unless the primary cause for the excessive pressure is corrected. Use of aperture pads (Fig. 195-13) may decrease the likelihood of recurrence by taking pressure off the original site. Shoes must be evaluated and modified if necessary.

**NOTE:** If the clinician is untrained or uncomfortable performing débridement, he or she may consider referral to a clinician comfortable performing it, especially for those patients with compromised circulation or diabetes; options include a competent podiatrist.

#### Combined Approaches

Therapy for these disorders can also include mechanical supportive orthotics (either functional or accommodative), nonsteroidal anti-inflammatory drugs (NSAIDs), accommodative footgear, digital or metatarsal pads, and accommodations made of moleskin, Cushlin

(Dr. Scholl's/Schering-Plough Healthcare Products, Memphis, Tenn), or silicone (Silipos [New York] or Spenco [Waco, Tex]; all available through Moore Medical Corp.).

#### **Surgical Treatment**

Surgical removal of bone exostosis, correction of digital deformities, osteotomies for elevation of depressed metatarsals, arthrodesis of midfoot, hindfoot, or ankle joint, or various joint-limiting procedures may be recommended when conservative therapies fail to provide lasting relief.

#### **Complications**

Secondary infections can occur with untreated corns or calluses. Ulcerations are a serious complication with diabetic neuropathy. Bursitis can occur with untreated lesions.

**Figure 195-13** Self-adherent aperture pads, usually placed over previously pared area to relieve pressure, often overlying a bony prominence. (From Ehrlich M, Nemer JA: Management of select podiatric conditions. In Reichman EF, Simon RR [eds]: Emergency Medicine Procedures. New York, McGraw-Hill, 2004, p. 1443.)

## WARTS (VERRUCAE PLANTARIS)

Verrucae plantaris ("plantar warts") are well-circumscribed, encapsulated, benign, tumorigenic, dermatotrophic lesions. The diagnosis is relatively simple, judging from appearance, the production of pain on lateral compression of the lesion, thrombosed tiny blood vessels, and pinpoint bleeding after débridement. Plantar verrucae appear different clinically from verrucae elsewhere because of being compressed and driven into the surrounding tissue.

Verrucae are encapsulated and well contained within the epidermis; the dermis is rarely involved. The lesion obliterates normal papillary skin lines. (This is an important diagnostic feature when treating warts. Often there is hyperkeratotic skin over the lesion. If this material is pared away after treatment and skin lines are then seen, the wart is considered resolved.) The appearance typically resembles grayish or brown papules with hypertrophic capillaries creating black or brown specks (end arteries, thrombosed capillaries) within the lesion. Plantar warts can occur singularly or in multiple clusters, which are referred to as *mosaic verrucae*. Smaller lesions surrounding the large centralized clusters are referred to as *satellite lesions*.

## **Etiology**

Verrucae plantaris is caused by the human papillomavirus.

## **Differential Diagnosis**

Warts are often confused with corns or deep calluses. Thrombosed tiny blood vessels and pinpoint bleeding after scalpel débridement are diagnostic hallmarks of verrucae plantaris. Other differential diagnoses include porokeratosis, epidermal malignancies (amelanotic melanoma), and various epidermal inflammatory conditions.

## **Treatment Options**

There are a plethora of treatment methods, including chemical cautery with various acids, caustic chemotherapy such as 5-fluorouracil, cryotherapy, infrared coagulation, electrosurgery, immunotherapy (including imiquimod), injections (bleomycin, Candida antigen), CO<sub>2</sub> pulsed-dye laser, and surgical excision or curettage. Even duct tape has been reported to be beneficial, with an 85% cure rate! (Also see Chapter 42, Wart [Verruca] Treatment.)

## **Techniques**

## Chemocautery

Scalpel débridement of all hyperkeratotic tissue should be performed first. After débridement, the application of various acids, such as trichloracetic acid 85%, salicylic acid 60%, or pyrogallic acid 25%, can be used. Careful protection of the surrounding normal integument is paramount (some clinicians paint surrounding tissue with fingernail polish). The acids are usually followed by an occlusive, adhesive dressing. The patient is then instructed to keep the area dry and intact for approximately 2 to 7 days. This procedure is repeated until normal skin lines are visualized. Treatment response times vary greatly with individuals. If there is minimal improvement after a reasonable number of treatments, another form of treatment, such as cryotherapy or other options as mentioned, should be considered.

#### Other Techniques

Specifics of treatment using other modalities are noted in the specific chapter dealing with each technique. (See Chapter 12, Approach to Various Skin Lesions; Chapter 14, Cryosurgery; Chapter 30, Radiofrequency Surgery [Modern Electrosurgery]; and Chapter 42, Wart [Verruca] Treatment.)

## **Complications**

Post-treatment pain can be controlled with ice, NSAIDs, and acetaminophen. Chemical burns can create a sterile abscess site; fortunately, these rarely become infected. Painful plantar scarring should be avoided because walking on scars can feel like stepping on a pebble.

## HAMMER (CLAW AND MALLET) TOES, BUNIONS (HALLUX VARUS AND VALGUS), AND BUNIONETTES (TAILOR'S BUNION)

Hammer, claw, and mallet toes are usually due to atrophy of the intrinsic muscles of the interphalangeal joints with subsequent loss of their stabilizing effect on the interphalangeal joints. As a result, the extrinsic muscles overpower the joints and pull them into permanent flexion or extension. Atrophy of the intrinsic muscles may be due to biomechanical faults, arthrosis, or constant pressure from tight shoes, resulting in toes being held in a constantly flexed or bent position; atrophy may also be due to other causes such as neuropathy from diabetes, alcoholism, or normal aging.

Hammer toes, like most nonacute foot deformities, are progressive. They start as flexible deformities where biomechanical control may be all that is necessary to prevent progression and even allow regression. A severe hammer toe deformity can indicate that there has been enough atrophy of the plantar capsule of the MTP joint to allow the metatarsal head to drop through the degenerated, torn capsule. Often this metatarsal head can be palpated as a hard bump on the bottom of the foot. It will also often result in the affected toes being splayed, and this can even be seen radiographically. Usually affecting the second toe, which is often the longest toe, this results in a permanently extended, dorsiflexed MTP joint. Subsequent pressure on the dorsum of the toe combined with an imbalance of muscles results in permanent plantar flexion at the proximal interphalangeal (PIP) joint and the appearance of a hammer. This also often occurs in the third toe. If the distal interphalangeal (DIP) joint also becomes permanently plantar flexed, it results in a claw toe. Claw toes can affect all the toes with the exception of the great toe (which does not have a DIP joint). A mallet toe occurs when only the DIP joint is flexed, and although it can involve any of the toes, it frequently affects only the second toe because it is often the longest.

Such structural abnormalities and deformities often result in increased pressure on the overlying skin and development of hyperkeratotic lesions. The hammer toe frequently shows flexion of the PIP joint and extension of the DIP joint.

Bunions and bunionettes also result from the effects of biomechanical faults, footwear, osteoarthritis/osteoarthrosis, or various other anatomic, physiologic, and hereditary conditions. Just like the thumb, the MTP joint of the great toe is a common site for osteoarthritis. Bunions involve the first metatarsal head, resulting in lateral deviation of the great toe and medial deviation of the MTP joint (also known as hallux abducto valgus, the terms derived from movement related to the mid-sagittal plane of the foot); bunionettes affect the fifth metatarsal head, resulting in medial deviation of the fifth toe (adduction) and lateral deviation (abduction) of the fifth MTP joint (also known as *tailor's bunion*).

## **Differential Diagnosis**

Trauma and infectious or other inflammatory diseases are possible causes for painful or deformed joints at all of these sites. Radiographs may be helpful not only for determining the magnitude of the problem but also for excluding other causes. Laboratory analysis may be helpful for ruling out infectious or inflammatory arthritis. The differential diagnosis of a bunion also includes bursitis of the first MTP joint; it can occur on the medial aspect of the joint.

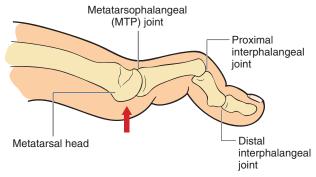

**Figure 195-14** Commercially available metatarsal pad; a similar pad can be cut from self-adherent felt.

#### **Techniques**

The initial treatment of hammer, claw, and mallet toes and bunions or bunionettes is to consider changing footwear (see Postprocedure Patient Education for how to fit a shoe correctly using the Brannock device). Shoes with a roomier toe box or use of thicker socks should minimize pressure against the inflamed, affected areas and allow them to heal. Hyperkeratotic lesions should be débrided or pared down. Padding and accommodative shields may help disperse local pressure and change balance. Precut metatarsal pads (Fig. 195-14) or bars are available or may be cut from 1-cm-thick felt (see Suppliers section). For hammer or claw toes, decreasing the degree of plantar flexion of the MTP joint by using metatarsal pads (Fig. 195-15), placed just proximal to the metatarsal head, may decrease symptoms. This is partially accomplished by decreasing the pressure on the dorsum of the distal toe(s) from the inside top of the shoe. If a metatarsal pad is used early, it may even prevent the development of hammer or claw toes. Attempts should be made to correct bony angulation or flexibility defects with padding or orthotics, to see if they are beneficial, before performing corrective surgery.

Bunion shields (Fig. 195-16) are also available or may be cut from 1-cm felt. With a bunion shield in place, padding can be placed between the first and second toe to decrease the angle of lateral deviation of the bunion.

NSAIDs may help with pain and inflammation. The use of ice massage in the inflamed area after exercise may be helpful. An inflamed MTP bursa can be drained and reinjected with a steroid. Even if there is no bursitis, injection of corticosteroid into the area of inflammation may be helpful.

**Figure 195-15** Adding padding such as a metatarsal bar may correct the angle of dorsiflexion of the MTP joint by putting pressure on the plantar aspect of the joint.

**Figure 195-16** Bunion shields are commercially available or can be cut from self-adherent felt.

For those failing local care, surgical options include resection of the phalangeal head (arthroplasty), joint fusion (arthrodesis), removing tissue, or moving tendons in the toe joint. A fixed toe joint deformity usually requires surgery to relieve pain and correct the deformity.

# METATARSALGIA, SESAMOIDITIS, AND STIFF TOE (HALLUX RIGIDUS)

Most commonly affecting the most distal portion of the metatarsal bone (i.e., the metatarsal head), metatarsalgia can affect the heads of any of the bones in the ball of the foot; however, it more commonly involves the second and third metatarsals. Frequently, a large callus is noted beneath the MTP joint. The ball of the foot is defined as the area between the arch of the foot and the toes.

Beneath the first metatarsal head are two sesamoid bones whose structure and function are similar to those of the patella. They may become painful as a result of overuse, a stress fracture, osteoarthritis, or chondromalacia. Because they are imbedded in the tendon, there is always an associated tendonitis. Plantar keratomas are frequently seen here, particularly with a plantar flexed first ray associated with high cavus foot deformity.

**EDITOR'S NOTE:** Anatomically, a "ray" is the digit plus the head and shaft of the respective metatarsal.

The great toe needs about 60 degrees of extension and 30 degrees of flexion for running and jumping sports; lack of flexibility causes discomfort. "Stiff toe," also known as *hallux rigidus*, is usually the result of a gradual process (over years) with a stiff, sore toe progressing to an inflexible first toe and pain even at rest. Although rheumatoid arthritis and gout can affect joint function, hallux rigidus is usually the result of a genetic predisposition combined with osteoarthritis. It can be a chronic, persistent cause of discomfort.

#### **Differential Diagnosis**

The location of hyperkeratotic lesions often helps differentiate between the possible causes of foot pain. Because of normal weight bearing, calluses are common under the first (and maybe second) and fifth MTPs; calluses between these locations may indicate other structural abnormalities of the foot or abnormal weight bearing, which may respond to orthotics or surgery.

The patient can often point to the most painful area. Pain beneath the second or third metatarsal heads usually indicates metatarsalgia. Pain beneath the first metatarsal head suggests sesamoiditis. Pain with sesamoiditis is usually gradual in onset; pain due to a stress fracture is usually immediate. A bursa can also form in this area, between the skin and usually the medial sesamoid bone, and result in bursitis. A torn ligament or arthritis of an individual

joint can cause similar pain. A radiograph can help distinguish between metatarsalgia and a metatarsal stress fracture, or sesamoiditis and a sesamoid stress fracture. On radiographs, the lateral sesamoid is often bipartite with smooth edges as opposed to jagged edges seen with a fracture. Radiographs of the metatarsal or sesamoid bones may initially be negative; however, serial radiographs taken 2 to 4 weeks later may reveal a fracture.

#### **Techniques**

Hyperkeratotic lesions should be débrided or pared. Use of a metatarsal pad placed just proximal to the second or third metatarsal head, under the diaphysis, should alleviate some of the symptoms of metatarsalgia; alternatively, the pad can be placed beneath the first metatarsal to force it to bear more weight (i.e., change the balance). Sesamoiditis also often responds to the use of metatarsal pads or a donut pad (a felt pad cut in the shape of a donut) to change the balance. Orthotics may prevent excessive pronation and decrease strain in the area. For a stiff first toe, early use of a metatarsal pad beneath the MTP joint may take off some of the stress and increase the leverage and range of motion of the first toe, not only decreasing but also possibly slowing the progression of symptoms. Attaching a pad to an ordinary insole of a shoe (or custom orthotic with first ray support, also known as first ray post) under the first MTP may also change balance, increase range of motion, and decrease symptoms. NSAIDs may help with pain and inflammation in all of these disorders. The use of ice massage in the inflamed area after exercise may be helpful. Injection of corticosteroid into the area of inflammation or intracapsularly may also be helpful; caution should be observed in young athletes with such an injection to prevent fat pad atrophy and increased capsular laxity.

#### POSTPROCEDURE PATIENT EDUCATION

Care should be taken to fit shoes properly. As a general rule, a proper-fitting shoe is longer and narrower than what most people wear. A Brannock device (Fig. 195-17A) is the most common instrument used for measuring shoe size. It comes in three sizes: men's, women's, and children's. The measurement for the widest

part of the shoe should be made just anterior to the first metatarsal head (Fig. 195-17B).

Shoes should also provide proper support, with steel shanks being preferable. It is simple to evaluate the effectiveness of any shank. Grasp the counter (heel) of the shoe with one hand and the toe box with the other hand (Fig. 195-18A), and attempt to twist the shoe. Observe the area of the shank, located between the center of the shoe and the heel; if that area deforms or twists (Fig. 195-18B), it will offer little support. A steel shank in a well-made shoe will result in little or no deformation with twisting.

# SHOULDER DISLOCATIONS

Jeffrey V. Smith

Dislocations of the shoulder are quite common. Approximately 50% of shoulder injuries in the emergency department are dislocations. Anterior dislocations are far more common than posterior dislocations. The four types of anterior dislocations account for 96% of all shoulder dislocations.

Of the four types of anterior dislocations, subcoracoid dislocations occur three times more frequently than all the others (subglenoid, subclavicular, and thoracic) combined. This chapter deals only with care of subcoracoid, anterior dislocations. All others should be treated with the assistance of an orthopedic surgeon.

The shoulder is the most flexible joint in the human body; consequently, it is the most unstable and most commonly dislocated joint. It is designed to enable a wide range of motion of the upper extremity, in all directions. To accomplish this feat, the actual bony articulation occupies only a very small part of the overall functional area of the joint. The glenohumeral joint surface and capsule are small sliding structures without significant fixed, ligamentous limitations. The tendons around the joint, making up the rotator cuff (Fig. 196-1), are the structures primarily responsible for the integrity of the joint and its complex function.

When the normal joint capsule and rotator cuff restraints are exceeded, the shoulder moves out of joint. Most frequently the clinician encounters a dislocation in which the humeral head has been pulled out of joint and is then held anteriorly and medially by spasm of the anterior chest wall muscles. This is the subcoracoid, anterior shoulder dislocation, usually occurring when an abducted, extended, and externally rotated upper extremity takes a major jolt. The resulting lever forces the proximal humerus anteriorly out of the glenoid socket. After the humeral head comes to rest under the coracoid process, the patient usually presents to the clinician in extreme pain with a nonfunctional arm. Dislocations may also occur during a seizure.

The patient will have a loss of the normal shoulder contour, with a step-off where the deltoid muscle used to be prominent. Instead, the acromion becomes very prominent. The contour of the humeral head may be noted in the anterior chest wall region. Clinically, a hollow can be appreciated beneath the acromion process, due to the missing humeral head. The arm will frequently be held in a slightly abducted, externally rotated posture. A neurologic deficit, most frequently involving the axillary nerve (provides innervation for shoulder abduction and sensation over the deltoid), may be noted on careful examination. Additional neurovascular compromise may be evident, but it is uncommon with subcoracoid, anterior dislocations.

Radiographs should be obtained; it is important to determine the presence (24% of anterior dislocations) or absence of a fracture before attempting to reduce the shoulder. Obtain standard radiographs of the shoulder. A single anteroposterior (AP) view of the shoulder will usually demonstrate the abnormal location of the humeral head. Another view at roughly 90 degrees will not only confirm the direction of humeral head movement, but help exclude a fracture or posterior dislocation. A lateral transcapular or a "Y"-type view will provide this information; an axillary view (Fig. 196-2)

is preferred by some clinicians but it is often difficult to get the patient to move his or her arm into the necessary position. Alternatively, in some obese individuals, a computed tomography (CT) scan may be necessary to determine the direction of the shoulder dislocation and the presence of concomitant fractures.

#### **INDICATIONS**

A subcoracoid, anterior shoulder dislocation is the indication for treatment.

#### **CONTRAINDICATIONS**

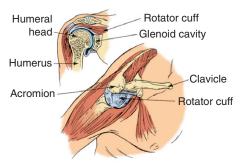

The following findings or conditions should generate an immediate orthopedic consult:

- A shoulder dislocation, other than a subcoracoid, anterior dislocation
- Any fracture dislocation of the shoulder
- Dislocations that are more than a few days old (higher risk of vascular injury, especially in older patients)
- Other fractures of the shoulder, neck, ribs, or upper extremity
- Prior orthopedic surgery for chronic or recurrent shoulder dislocations
- Shoulder dislocations in children (if ossification centers are not fused, there is usually an associated Salter-Harris fracture)

**EDITOR'S NOTE:** A patient with neurovascular compromise (other than mild axillary nerve sensory defect) due to shoulder dislocation should undergo immediate reduction. Although it is beyond the scope of this book, even inferior or posterior shoulder dislocations should undergo immediate reduction if the distal pulse is compromised. Although immediate orthopedic assistance is optimal, it may not always be possible.

#### **EQUIPMENT AND SUPPLIES**

- Stretcher
- Washcloth or small towel
- Soft restraints such as sheets or blankets
- Cloth tape, gauze or elastic bandage, padded wrist restraint or commercially available device for hanging weights from wrist
- Weights (5 to 15 lbs) or bucket (½ to 1 gallon size and adequate tap water or intravenous [IV] fluid)
- Intra-articular anesthetic (10 to 20 mL of 50:50 mixture 1% or 2% lidocaine with sterile saline), antiseptic solution (e.g., chlorhexidine, povidone—iodine), 10- to 20-mL syringe, 25-gauge, 2½-inch needle
- Procedural sedation forms, consent, equipment (see Chapter 2, Procedural Sedation and Analgesia) and medications (e.g., analgesia, muscle relaxant, narcotics, benzodiazepines, reversal agents)
- Shoulder immobilizer or sling and swath

**Figure 196-1** Anatomy of the shoulder joint and how the tendons of the muscles (supraspinatus, infraspinatus, subscapularis, and teres minor) form the rotator cuff. Also see Chapter 185, Musculoskeletal Ultrasonography, and Chapter 192, Joint and Soft Tissue Aspiration and Injection (Arthrocentesis).

#### PREPROCEDURE PATIENT PREPARATION

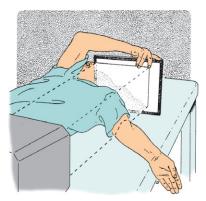

Patients should be informed about the indications for shoulder reduction, as well as any alternatives and possible complications. They should know what to expect and try to relax as much as possible. If a local anesthetic injection will be used, the patient can be reassured that this should decrease the discomfort. Informed consent should be obtained appropriate for the procedure(s) to be performed.

#### **PRECAUTIONS**

To be successful, this procedure takes some time and relaxation—on the part of both the patient and the clinician. The procedure is easy, but trying to rush it may result in an unsuccessful episode. One exception is the dislocation witnessed by the sports medicine clinician; if the dislocation is not associated with high-energy forces, some clinicians will reduce the shoulder immediately, fieldside, without radiographs and before the muscular spasm can occur.

#### **TECHNIQUE**

There are a number of available techniques, all designed to apply gentle and persistent tension on the spasmodic chest wall muscles, to elongate them, and to reestablish the mobility of the humeral head. Once this is done, the humeral head will usually track or be gently manipulated back into the glenoid fossa. The patient is probably best served by the simplest technique, the one that minimizes both operator and patient stress. Typically, this is the Stimson technique, wherein weight loading and time can be used to gently stretch the muscles and reduce the joint. Certainly, this is the least

**Figure 196-2** Radiographs should include a view at 90 degrees from the anteroposterior view, such as this axillary view. Such a projection helps document the direction (anterior vs. posterior) of the shoulder dislocation.

traumatic technique for the shoulder and should help minimize the chances of a fracture developing related to the reduction process.

Other techniques may also be successful. Although many have been described in the literature, all of the listed techniques have been tested and are effective in a situation where the clinician is willing to take his or her time with the reduction. Experience suggests that the clinician should not attempt more than two reduction procedures. If the second attempt is unsuccessful, the resultant muscle spasm will likely prevent closed reduction in a safe manner. Call the orthopedic surgeon if the second attempt is unsuccessful.

#### Intra-articular Anesthetic

Some experts recommend the injection of intra-articular anesthetic with every shoulder reduction (see also Chapter 192, Joint and Soft Tissue Aspiration and Injection [Arthrocentesis]). It can also be used if procedural sedation is contraindicated.

- 1. Identify the hollow area where the humeral head used to be located, 2 cm (two fingerbreadths) directly inferior to the lateral border of the now prominent acromion process. Apply antiseptic solution to the skin over this area and allow to dry.
- 2. Using sterile technique, insert the 25-gauge, 2½-inch needle into this area, perpendicular to the skin, to a depth of 2 cm. Inject 10 to 20 mL of a 50:50 mixture of local anesthetic and sterile saline solution.

#### Stimson Technique

- 1. Using this technique, procedural sedation is often unnecessary; some experts use the injected local intra-articular anesthetic. Also, there are reports of a 96% success rate, and there is no need for an assistant. Conversely, the prone position may be impossible to use because of other injuries; procedural sedation is also not recommended because the prone position may interfere with respiration. Procedural sedation is even relatively contraindicated because of the prolonged nature of this technique.
- 2. The patient is placed in the prone position on a stretcher with the affected arm hanging over the side. A rolled-up washcloth or small towel can be placed beneath the coracoid process and pectoralis major muscle as needed for comfort. The clinician may want to wrap soft restraints (sheets or blankets) around the bed and the patient at the hips to prevent him or her from falling off the stretcher. A weight (usually from 5 to 15 lbs) is affixed to the wrist to provide longitudinal, sustained traction. Wrapping tape, a gauze or elastic bandage, or a padded wrist restraint around the wrist should provide secure fixation of the weight to the limb. Commercial devices are also available for securing and hanging a weight from the wrist. A bucket of water can be used if weights are not available; the disadvantage for the patient is having to hold the bucket for a considerable length of time. IV fluid can be used to gradually increase the traction as the bucket fills up (Fig. 196-3).
- 3. With time (usually 15 to 30 minutes) and relaxation, the shoulder will usually reduce itself. Occasionally (perhaps after 30 minutes), the clinician will need to facilitate the reduction by grasping the forearm and gently twisting it, externally first and then internally, while the arm is still under traction. Either the patient or clinician may feel a "clunk" as the joint is reduced, and there may be brief fasciculations of the deltoid muscle. However, the reduction may be more subtle; if the patient can touch his or her nose or the opposite shoulder with the index finger of the affected upper extremity, it usually indicates a successful reduction.
- 4. After the shoulder has been reduced, hold the limb in internal rotation against the abdomen and adduction (humerus against the lateral trunk) with a shoulder immobilizer or sling and swath

**Figure 196-3** Gentle, sustained distal traction can provide an effective means for closed reduction of an anterior dislocation. As the intravenous fluid slowly empties into the bucket, the traction force gradually increases.

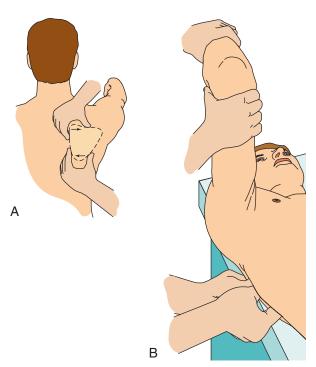

- device. A careful postreduction neurovascular assessment is required.
- 5. While keeping the shoulder immobilized, obtain appropriate postreduction radiographs to determine whether adequate reduction of the joint surfaces has been achieved. A congruous-appearing joint without significant distraction (interposed tissue) between the glenoid and the humerus should be noted. Occasionally, comparison shoulder radiographs or a postreduction CT scan may be required. Some recent studies question the value of postreduction imaging, but in most communities it is still the standard of care.

#### **Scapular Manipulation Technique**

The patient may or may not require analgesia or injected anesthesia for this technique because there is somewhat less manipulation required (and less chance of injury) than with most other techniques. Using this technique, the glenoid fossa is repositioned rather than just the humeral head. Scapular manipulation may be performed with the patient prone, sitting, or supine. When the patient is prone or supine, traction is applied to the arm by an assistant (or by attached weights if the patient is prone). The shoulder is gently and gradually flexed by an assistant to a 90-degree position, and from 5 to 15 lbs of traction is required. The clinician then uses one hand to rotate the inferior aspect of the scapula upward and medially, and the other hand to rotate the superior aspect laterally (Fig. 196-4). When the patient is sitting, an assistant provides forward traction on the affected arm with countertraction against the head of the humerus to obtain the same 90 degrees of flexion. From behind the patient, the clinician manipulates the scapula as described previously. If reduction does not occur within 1 to 3 minutes, a small degree of dorsal displacement of the inferior scapular tip may be helpful. At this point, slight external rotation of the humerus by an assistant while traction is maintained on the humerus and the scapula is being manipulated may also be helpful. There have never been complications reported from using this technique; however, it is a cumbersome process. Reduction may also be very subtle when accomplished by this technique, without a perceived "clunk." This technique may be used when other injuries limit repositioning the

#### Hennepin Technique

The Hennepin technique is named after the Hennepin County Emergency Medical Center (Minnesota), where the technique was

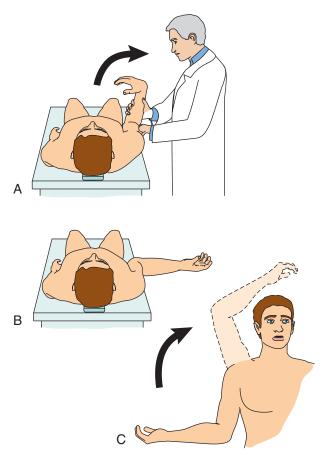

**Figure 196-4** Scapular manipulation technique. **A,** An assistant flexes the patient's arm (or if the patient is prone, it can be flexed by gravity and weights, as with the Stimson technique). It must be slowly brought to a 90-degree position. The clinician then rotates the inferior scapular tip upward and medially, and the superior aspect laterally (clockwise on the right shoulder when viewed from back, counterclockwise on the left shoulder). **B,** The same technique with the patient in supine position. With the patient's shoulder and elbow both flexed 90 degrees, and the shoulder adducted, gentle upward pressure is maintained by an assistant while the scapula is manipulated as described.

first described. It is the technique preferred by some authors for anterior shoulder dislocations. There is less manipulation than with most other techniques, a lower probability of neurovascular or musculoskeletal damage, and little or no need for analgesia (although an injection of intra-articular anesthesia may be beneficial). The patient is seated upright, reclining at 45 degrees, or supine. With the clinician stabilizing the patient's elbow joint of the affected arm with one hand, the clinician's other hand is used to grasp the patient's wrist. Slowly (it can take up to 10 minutes to accomplish), the patient's forearm is externally rotated until there is 90 degrees of external rotation (Fig. 196-5). The procedure should be stopped if the patient experiences pain or discomfort, but do not release the arm or allow it to return to its original position. Usually, after allowing the musculature or spasm to relax, the procedure can be continued without analgesia. If pain or discomfort persists, the patient may require analgesia. The reduction usually occurs by the time the forearm has reached 90 degrees of external rotation; if it has not, the arm is slowly elevated. Occasionally, it will need to be elevated to the level that the patient can touch his or her contralateral ear (over the head). If reduction still does not occur, the humeral head is gently manipulated toward the glenoid until it reduces.

#### **Modified Kocher Maneuver**

The modified Kocher maneuver is similar to the Hennepin technique. The patient is placed supine with the arm of the affected shoulder over the edge of the gurney, and analgesia or injected anesthesia is provided if necessary. The patient's forearm, with the

**Figure 196-5** Hennepin and modified Kocher techniques. Both techniques start with the elbow flexed to 90 degrees ( $\mathbf{A}$ ), and then fully externally rotated ( $\mathbf{B}$ ). For the modified Kocher, the forearm is then returned to complete internal rotation while gentle shoulder joint pressure is applied. The Hennepin technique ( $\mathbf{C}$ ) is continued from ( $\mathbf{B}$ ), if necessary, with elevation of the arm and manipulation of the joint posteriorly until the arm is overhead and the dislocation is reduced.

elbow held at 90 degrees, is then rotated externally (abducting superiorly) over at least a 5-minute period (see Fig. 196-5), with simultaneous gentle downward pressure applied on the dislocation. After the arm reaches 120 degrees of rotation, the arm is brought back to internal rotation, at which time the reduction usually occurs.

#### Milch Technique

With the patient sitting or supine, the arm is moved to 10 to 20 degrees of forward flexion with slight abduction. One of the clinician's hands is then used to gently guide the patient's arm (grasping at the elbow) in this slightly abducted position and using slight traction, until it is directly overhead (Fig. 196-6). The patient may be able to move the arm without assistance to this position; however, there is usually too much pain and spasm. While this is occurring, the clinician's other hand is placed on the humeral head to prevent it from moving downward. When the arm is located directly overhead, the rotator cuff muscles are all in alignment, and all crossstresses are eliminated. Using just his or her thumb, the clinician should be able to direct the humeral head superiorly over the rim of the glenoid and into the fossa. Otherwise, abduction of the arm and outward traction at the shoulder are increased and the arm brought through a full, lateral downward arc. Reduction is usually signified by an audible or palpable "clunk."

#### **Fulcrum Technique**

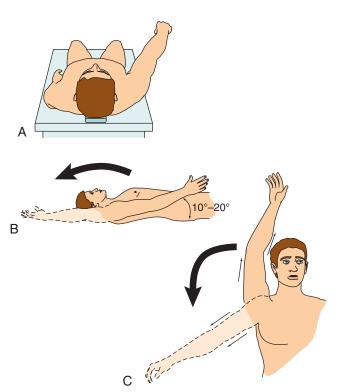

With the patient supine or sitting, a firmly rolled towel, sheet, or blanket, 6 to 8 inches in diameter, is placed as a fulcrum within the axilla of the affected shoulder. The distal humerus is used as a lever and is adducted gently, with simultaneous posterolateral manipulation of the humeral head. This technique increases the forces applied; therefore, the risk of complications is increased.

#### **Boss-Holzach-Matter Technique**

The patient sits against the maximally raised head of a gurney and wraps his or her forearms around the ipsilateral knee, which is flexed at 90 degrees. The head of the gurney is then lowered. The patient is asked to hyperextend the neck while leaning back and shrugging the shoulders anteriorly. This technique reportedly does not require analysesia.

#### **Hippocratic Technique**

Because the Hippocratic technique is no longer recommended, it is included only for historical interest. The clinician places his or her foot against the chest wall to provide countertraction and then manipulates the arm. This technique can cause serious neurovascular trauma.

**Figure 196-6** Milch technique. **A,** The arm is started at 10 to 20 degrees of flexion and slight abduction. **B,** Elevation continues slowly, with slight distal traction, until the arm is directly overhead. The patient may be able to raise the arm on his or her own. The head of humerus should be held immobile at this stage of maneuver. **C,** If no reduction occurs with gentle, direct manipulation of the head of the humerus, the arm is then slowly brought through a full, lateral downward arc, maintaining constant outward traction until reduction occurs. Note that this is the only step of the procedure in which outward traction is maintained.

#### **COMPLICATIONS**

If the shoulder dislocation proves *irreducible*, an orthopedic surgeon should be consulted and the use of general anesthesia considered. *Fracture* (due to the dislocation or reduction [iatrogenic]) and *neurovascular damage* are ever-present risks. Up to 50% of anterior dislocations have a Hill-Sachs deformity, an impaction fracture defect in the posterolateral portion of the humeral head. A Bankart lesion may also be noted, which is an avulsed fragment of the glenoid labrum with contiguous bone. Both lesions tend to get worse the longer the humeral head remains dislocated.

Many clinicians obtain postreduction radiographs to document reduction of the joint, any injury associated with the reduction, and any bony abnormalities such as the aforementioned lesions.

Another risk after a shoulder dislocation is *redislocation*. In patients followed for 10 years, age at initial dislocation was the only predictor of recurrence; duration of subsequent immobilization had no effect. *Rotator cuff tears* and *hemarthrosis* are more common with inferior dislocation and in patients older than 60 years of age. To avoid serious *complications of procedural sedation*, adequate respiratory support measures and monitoring should be present. Patients need to be observed after such sedation to ensure they are awake, alert, and oriented before discharge.

#### POSTPROCEDURE EDUCATION AND CARE

Patients may need oral analgesic medications, possibly even narcotics, for a few days. Those younger than 20 years of age should be immobilized for 3 weeks, patients aged 20 to 40 years should be immobilized for 1 to 2 weeks, and patients older than 60 years should have less than 1 week of immobilization. Appropriate clinical, neurologic, and radiographic follow-up examinations should be made throughout this time to confirm maintenance of the reduction. After the designated period of immobilization, assign a gentle strengthening program, with particular emphasis on the shoulder internal rotators. Unrestricted external rotation, abduction, and lifting activities are usually not permitted for a period of 3 months. Even combing the hair combines external rotation and abduction and should be avoided indefinitely on the side of dislocation. With recurrent dislocations, an arthrogram, CT arthrogram, magnetic resonance imaging, or arthroscopy might be warranted to help identify an anatomic variant that might make the patient more prone to redislocation. Patients with peripheral neuropathies, syringomyelia, and psychiatric histories may be more prone to dislocating their shoulders, and these underlying conditions should be considered in patients with repeated dislocations.

#### **CPT/BILLING CODES**

23650 Closed treatment of shoulder dislocation, with manipulation, without anesthesia

23655 Closed treatment of shoulder dislocation, with manipulation, requiring anesthesia

#### **ICD-9-CM DIAGNOSTIC CODES**

718.01 Articular cartilage disorder, shoulder region (old rupture of ligaments)

718.11 Loose body in joint, shoulder region

718.31 Recurrent dislocation of joint, shoulder region

831 Dislocation of shoulder

The following five-digit subclassification is for use with category 831:

O Shoulder, unspecified (humerus NOS)

1 Anterior dislocation of humerus

2 Posterior dislocation of humerus

3 Inferior dislocation of humerus

4 Acromioclavicular (joint) (clavicle)

9 Other (scapula)

831.0 Closed dislocation

831.1 Open dislocation

# TRIGGER-POINT INJECTION

Ashley Christiani

Myofascial pain is among the most common complaints for which patients seek care. In many cases, there is a defined, reproducible site of tenderness in the affected muscle, called a *trigger point*, that can be targeted for relief of pain and spasm. Trigger points (TrPs) may be effectively treated in the office through the TrP injection technique described here. Understanding TrP pathology and treatment can aid the clinician in addressing one of the most common and debilitating acute complaints encountered in the outpatient setting.

The term *trigger point* was coined by Dr. Janet Travell in 1942 to describe the clinical finding of a painful nodule in an indurated cord or "taut band" of muscle (Fig. 197-1). According to the American College of Rheumatology, TrPs should be painful to palpation with 4 kg of pressure, approximately the point at which the examiner's fingernail would begin to blanch. The taut band of muscle fibers may respond during palpation or needle activation with a local twitch response (LTR). Although the LTR phenomenon is not always visible, when present this response predicts an effective response to TrP injection.

It is thought that any one of the over 600 striated muscles in the human body can develop TrPs, although not all can be accessed by direct palpation. Examples of the most common TrPs are shown in Figure 197-2. TrPs can form in response to an acute event such as a sudden strain placed on an already contracted muscle, or in the context of insidious, repetitive strain. TrPs are commonly classified as "active" or "latent." Active TrPs (Box 197-1) are symptomatic, causing pain, stiffness, decreased range of motion, and referred symptoms such as paresthesias or a disturbance in motor or autonomic function. The pain experienced by patients may be well localized or diffuse, ranging in character from a dull ache to sharp, burning, and debilitating. Motor dysfunction includes muscle weakness and easy fatigability as well as spasm of other muscles in the kinetic chain. Examples of autonomic dysfunction include abnormal sweating, lacrimation, and salivation, pilomotor disturbance, mild edema, imbalance, dizziness, and tinnitus. Palpation of active TrPs typically reproduces the patient's symptoms. Latent TrPs may also cause stiffness and restriction of motion but are generally not noted by the patient to be painful until directly palpated by the examiner or when "unmasked" during the treatment of active TrPs.

Approximately 20% of patients with active TrPs also have fibromyalgia; it is important to differentiate this subset (Table 197-1) because patients with fibromyalgia usually have diffuse pain that may be better managed with systemic regimens and physical therapy as opposed to localized TrP injections. Performing a TrP injection in patients with fibromyalgia may actually worsen the pain. It should be noted that TrPs are frequently located near a bony prominence, moving part, or where a muscle or tissue slides, whereas the tender points associated with fibromyalgia are often located in an area where the tissue is not subject to any local stress.

Trigger-point injection may be performed quickly and effectively in the office setting to treat myofascial pain, producing immediate and often long-term results, especially when combined with comple-

mentary therapies such as physical therapy, exercise, massage, "spray and stretch," or ergonomic retraining. TrP injection is thought to work by causing a temporary relaxation of the taut muscle, allowing for improved local perfusion, replenishment of the adenosine triphosphate (ATP) required to release actin-myosin chains, and clearance of noxious metabolites. In turn, this breaks the paintension cycle. Studies have demonstrated that it is the mechanical stimulation of the TrP by the needle that releases the muscle spasm, whereas the substance injected provides only adjuvant therapy. Response rates are similar regardless of the substance injected; whether it is saline, a steroid, a local anesthetic, or a paralytic agent such as botulinum toxin injected, none has proven to be more effective than "dry needling" alone. However, the latter two substances may produce longer-lasting results because of caustic damage to the muscle. Injection of local anesthetic offers the additional benefit of significantly reducing postprocedure pain compared with saline or dry needling, without adding undue risk to the procedure. Most authorities recommend the use of 0.25% to 1% lidocaine without epinephrine or 2% procaine diluted to 0.5% for TrP injections. We recommend against the use of steroids for TrP injection.

#### **INDICATION**

Focal tender area identifiable by palpation without other identifiable neurologic or musculoskeletal findings or pathology is the indication for treatment. The tender area should be accessible by needle without significant risk.

#### **CONTRAINDICATIONS**

#### **Absolute**

- TrP not safely accessible by needle
- Cellulitis or other loss of skin integrity in area overlying TrP

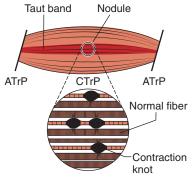

#### Relative

- Poorly controlled psychiatric disorder
- Resuscitation equipment not available
- Poorly controlled systemic illness that may compromise healing or predispose to infection
- Bleeding disorder, including anticoagulant use
- Severe fibromyalgia or presence of numerous TrPs
- History of keloid formation
- Highly anxious or needle-phobic patient

# PREPROCEDURE PATIENT PREPARATION AND EVALUATION

#### **History and Physical Examination**

Screening should include any history of trauma, fibromyalgia, collagen vascular disease, inflammatory condition, bleeding disorder,

**Figure 197-1** Trigger point complex in muscle. ATrP, attachment trigger point; CTrP, central trigger point. (From Simons DG, Travell JG, Simons LS: Travell & Simons' Myofascial Pain and Dysfunction: The Trigger Point Manual, 2nd ed. Philadelphia, Lippincott Williams & Wilkins, 1999.)

hypothyroidism, diabetes, hepatitis C (often associated with generalized myalgia), and any other systemic diseases or chronic conditions. The physical examination should include evaluation of the affected musculature and any associated musculature innervated by the same spinal segment to identify active and latent TrPs and to assess for other potential causes of pain. Significant muscle atrophy or sensory deficit is not commonly seen in isolated TrP phenomena and should alert the clinician to other etiologies. Tender musculature should be palpated slowly and deliberately for taut bands and tender nodules with the muscle in a relaxed position. TrPs are commonly found in the mid-belly of the muscle where contraction is most acute, but the entire muscle from origin to insertion should be examined. Muscles that can be accessed in only one plane can be explored by flat palpation (Fig. 197-3), whereas those that can be partially enclosed in the fingers can be examined with the pincer

# Box 197-1. Diagnostic Criteria for Active Trigger Points

- Pain recognition (patient identifies pain at the TrP as the pain he or she has been experiencing)
- Presence of an exquisitely tender nodule in a palpable taut band
- Referral of pain or symptoms in predictable pattern on palpation
- Painful limitation of range of motion

#### Helpful if Present

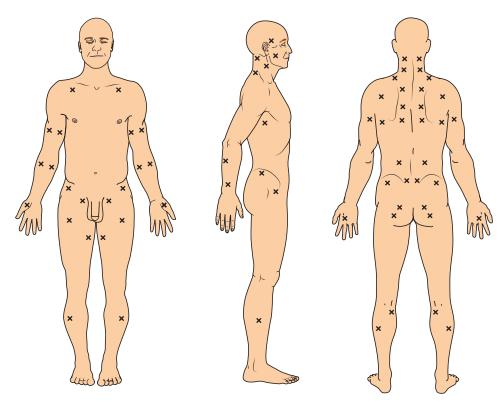

- Local twitch response observed when TrP is stimulated
- Associated autonomic responses triggered with palpation of TrP
- Electromyographic demonstration of spontaneous electrical activity in region of tender nodule in the taut band

TrP, trigger point.

grasp (Fig. 197-4). As discussed previously, palpation of an active TrP generally elicits wincing or involuntary guarding by the patient and may generate an LTR. The history and physical examination should also include investigation of mechanical etiologies and risk factors for development of recurrent TrPs such as leg length discrepancy, scoliosis, poor posture and body mechanics, or chronic trauma caused by carrying heavy items such as handbags, work equipment, or infants or young children. Behavior modification and physical therapy may help prevent further injury in these cases.

#### **Informed Consent**

Provide the patient with a detailed explanation about the procedure and its potential risks, benefits, and alternatives (specific to the condition being treated), and obtain informed consent. If multiple

**Figure 197-2** Anterior, lateral, and posterior views of common trigger points. (From Simons DG, Travell JG, Simons LS: Travell & Simons' Myofascial Pain and Dysfunction: The Trigger Point Manual, 2nd ed. Philadelphia, Lippincott Williams & Wilkins, 1999.)

TABLE 197-1 Myofascial Pain due to Trigger Points versus Fibromyalgia				
Myofascial Pain Due to Trigger Points	Fibromyalgia

fibromyalgia

\*Widespread pain denotes pain that is bilateral and involving both the upper and lower body. Widespread pain must have been present for 3 months.

active TrPs

<sup>†</sup>Pain in at least 11 of the 18 specific tender points must be present. These tender points (bilateral) include the *occiput* (at suboccipital insertion), *lower cervical spine* (C5–C7 levels), *trapezius* (midpoint of upper border), *supraspinatus* (above scapular spine near medial border), *second rib* (at second costochondral junction), *lateral epicondyle* (2 cm distal to the epicondyle), *gluteus* (upper, outer quadrants of buttocks), *greater trochanter* (posterior to the trochanteric prominence), and *knee* (at the medial fat pad proximal to joint line).

Adapted from Simons DG, Travell JG, Simons LS: Travell & Simons' Myofascial Pain and Dysfunction: The Trigger Point Manual, 2nd ed. Philadelphia, Lippincott Williams & Wilkins, 1999.

TrPs are present on examination, they are generally best treated on the same visit unless they are too numerous (in which case other treatment modalities may be preferable). Explain to the patient that the relief resulting from the treatment can be followed by pain greater than the original pain either in the same location or as an "unmasking" effect with pain in other untreated muscle groups, and that follow-up injections may be appropriate.

#### **Patient Preparation**

If not medically contraindicated, it may be advisable to discontinue aspirin or other anticoagulants at least 3 days before the procedure to minimize bleeding. Patients who are anxious may benefit from pretreatment with a mild oral anxiolytic. In preparation for the procedure, the patient should generally be supine with pillows provided for rotational support, as needed, to minimize risk of vasovagal response.

#### **EQUIPMENT**

- Alcohol wipes.
- Gloves (nonsterile).
- Several gauze pads and Band-Aids.
- Ball-point pen (with retracted nib) or skin marker.
- Lidocaine (0.25% to 1% without epinephrine), procaine (2% diluted to 0.5%), or bupivacaine (0.125% to 0.25%).
- Sodium bicarbonate 5% to 8.4% solution, for injection, available in 50-mL bottles with 50 mEq/50 mL, may be added as a buffer to local anesthetic. Add 1 mL per 10 mL of anesthetic.
- 25- to 27-gauge needle, depending on site to be injected. A 27-gauge, 1½-inch needle is usually sufficient for the upper torso; a 25-gauge, 3½-inch spinal needle may be required for large back or leg muscles.

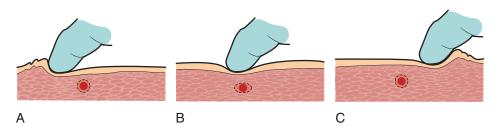

Figure 197-3 Flat palpation technique. A, Index finger pushes skin to one side. B, Fingertip sweeps across the muscle to feel the taut band rolling beneath. C, The skin is pushed to the other side, completing the movement. (From Simons DG, Travell JG, Simons LS: Travell & Simons' Myofascial Pain and Dysfunction: The Trigger Point Manual, 2nd ed. Philadelphia, Lippincott Williams & Wilkins, 1999.)

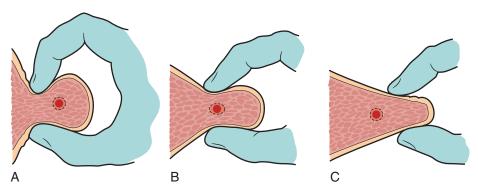

Figure 197-4 Pincer grasp technique. **A,** Muscles that are accessible from two sides may be gripped between the thumb and fingers. **B,** The taut band may be felt as it is rolled between the digits. **C,** The edge of the taut band is palpable as it rolls beneath the fingertips, often inciting a local twitch response. (From Simons DG, Travell JG, Simons LS: Travell & Simons' Myofascial Pain and Dysfunction: The Trigger Point Manual, 2nd ed. Philadelphia, Lippincott Williams & Wilkins, 1999.)

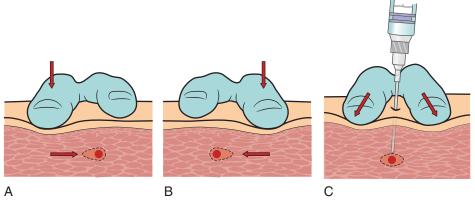

Figure 197-5 Localizing and securing a trigger point (TrP) for injection. A and B, The use of alternating pressure helps to precisely localize the TrP. C, The TrP is held in place with downward pressure and gentle traction to keep it from sliding away from the needle. (From Simons DG, Travell JG, Simons LS: Travell & Simons' Myofascial Pain and Dysfunction: The Trigger Point Manual, 2nd ed. Philadelphia, Lippincott Williams & Wilkins, 1999.)

- 3-, 5-, or 10-mL syringes.
- Resuscitation equipment (as with any injection).
- Pillows (optional).
- Vapocoolant spray such as ethyl chloride for topical anesthesia (optional).

#### **TECHNIQUE**

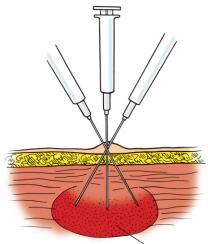

- 1. Place the patient in a comfortable or recumbent position to protect the patient in the event of a vasovagal reaction.
- 2. Identify and mark the TrP.
- 3. Using an 18-gauge needle, draw up 5 to 10 mL of 1% lidocaine, 0.5% procaine, or 0.125% to 0.25% bupivacaine into the syringe. If desired, sodium bicarbonate solution may be added in a 1:10 ratio by volume.
- 4. Replace the needle with a 25- to 27-gauge needle as appropriate for TrP depth and muscle thickness.
- 5. Prepare the skin with an antiseptic solution or alcohol.
- 6. Reidentify the TrP with gloved hands, observing aseptic technique. The TrP should be stabilized between the fingers of the nondominant hand with downward pressure and slight tension on the skin surface (Fig. 197-5).
- 7. If superficial anesthesia is desired, 0.25 to 0.50 mL of local anesthetic may be injected into the skin to produce a wheal or a vapocoolant spray such as ethyl chloride may be applied to the site while maintaining stabilization of the TrP.
- 8. Slowly advance the needle perpendicular to the skin toward the TrP. Avoid infiltrating anesthetic until the needle is fully advanced into the target. A slight resistance should be felt on reaching the fascial plane of the muscle, at which point it is helpful to pause and inject 0.2 mL of solution. A gentle "pop" may be felt as the needle is advanced into the muscle itself. Once the needle is in the TrP site, observe for LTRs and aspirate to confirm a nonvascular position.
- 9. Inject 0.1 to 0.2 mL of solution once the TrP is located. Withdraw the needle slightly and reinject the site several times in a fanlike pattern, injecting as the needle is withdrawn (Fig. 197-6). No more than 2 mL should be injected into any particular muscle region. The patient will usually experience immediate relief if the injection is properly located.
- $10. \,$  Remove the needle and wipe the skin clean with a disinfectant.
- After withdrawing the needle, massage the entire area to diffuse the anesthetic and check for pain relief. Put the affected muscle complex through full range of motion.

#### **COMPLICATIONS**

- Vasovagal symptoms or syncope.
- Skin infection.
- Injury to nerves, vasculature, or other nearby structures.
- Rebound pain.
- Reactions to the local anesthetic or steroid.
- Hematoma formation, bleeding, compartment syndrome.
- Pneumothorax (rare). Special care should be observed when injecting muscles of the thorax. Use pincer grasp when possible. Carefully select appropriate needle length. Use a tangential (instead of vertical) vector for the needle. It may be helpful to have the patient hold his or her breath during injection.

#### **POSTPROCEDURE CARE**

Active TrPs are generally treated with a series of injections over the course of days to weeks. Injections may be repeated as frequently as every 3 to 4 days. Temporary discomfort due to the injection itself may be treated with cold compresses or oral anti-inflammatory drugs. Patients should be instructed to report any redness, pus, streaking,

Area of identified tenderness

Figure 197-6 Injection of a trigger point.

increased pain, or other concerns. Activity modification and ergonomic retraining may help to avoid reinjury.

#### **PATIENT EDUCATION GUIDE**

# Intraosseous Vascular Access

Raymond F. Jarris, Jr. • Grant C. Fowler

One of the most frustrating and difficult challenges faced by a clinician is the establishment of vascular access in the critically ill patient. Establishment of peripheral intravenous (IV) access is often difficult in the patient who is in shock or cardiac arrest, and is notoriously difficult in the small pediatric patient. For children younger than 5 years of age, thin bones and a vascular marrow make intraosseous vascular access (IOVA) a fairly simple alternative. For years, plain hypodermic needles, spinal needles, or bone marrow aspiration needles (e.g., Jamshidi) were used for IOVA. Eventually, special IOVA needles with a handle and a screw tip were developed. Later models were developed with flanges to better secure them to the patient with tape after insertion. Recently, kits combining IOVA needles with either a small, portable, batterypowered drill or a spring-loaded disposable needle gun have increased the use of this technique in adults. In fact, many hospitalists now use IOVA in adults more often than in children. Using IOVA, after the needle traverses the cortex, the venous plexus in the marrow cavity (Fig. 198-1) functions as a rigid "vein" or conduit for fluid; it does not collapse with hypovolemia or even shock. This procedure is now so successful that many national and international organizations have recommended its use as the primary or secondary method of obtaining and maintaining vascular access in the critically ill patient. Use of IOVA is also increasingly common and accepted as an alternative to a central line for short-term infusions in nonemergent situations.

IOVA was originally described in the 1920s. However, with the introduction of plastic catheters and improved peripheral IV access skills, the need and interest for IOVA diminished. In the 1980s, IOVA saw a resurgence in use as a rapid method for vascular access in pediatric shock emergencies. It was also studied for use with regional anesthesia in Europe. IOVA has now been studied and proven to be a safe, reliable, and rapid temporary method for vascular access in adult shock emergencies, especially compared with percutaneous IV access. The American Heart Association, the American Academy of Pediatrics, and the American College of Surgeons recommend vascular access by IOVA in emergency situations when venous access is not immediately possible. Any medication or fluid that can be given IV can also be administered by IOVA. After a 5- to 10-mL flush with normal saline, medications are immediately absorbed into the systemic circulation; drug concentrations and onset of action match those given through a central venous line during cardiopulmonary resuscitation (CPR). In addition to serving as a route for fluid administration, the IOVA needle may be used for obtaining blood type, cross-matching, and blood chemistry determinations from the marrow cavity. Serum electrolyte, blood urea nitrogen, creatinine, glucose, and calcium levels are very similar to those in samples obtained from an IOVA aspirate.

One disadvantage of IOVA is the temporary nature of the procedure (it should not be used for more than 24 to 48 hours). Another, disadvantage is that infusion rates may be limited; however, rates can also reach more than 150 mL/min with a 16-gauge needle and a pressure infusor bag (blood pressure cuff inflated to 300 mm Hg

around the IV fluid bag), an infusion pump, or with forceful manual pressure. The rate-limiting factor is usually the size of the marrow cavity. IOVA also is not universally successful; however, in the past, success rates were limited in older children and adults because needles often bent when attempting to penetrate thicker bones. Success rates have improved since the development of kits specially designed for this procedure.

One retrospective study of pediatric cardiopulmonary arrest patients revealed that, although the time to obtain peripheral IV was occasionally minimal, the average time was a disappointing 7.9 ± 4.2 minutes. The overall peripheral IV success rate was only 17%. Of all techniques used, the success rate was highest with IOVA (83%), next most successful was surgical cutdown (81%), and central venous line placement (CVP; 77%) came in third. The average time required to establish vascular access was 4.7 minutes for IOVA (using older equipment not specially designed for this procedure), followed by 8.4 minutes for CVP, in turn followed by 12.7 minutes for venous cutdown. Using newer kits specially designed for IOVA, the success rate has significantly improved over the prior 83%.

In the cardiopulmonary arrest situation, it is reasonable to use IOVA as the initial approach for vascular access because of the high success rate and the rapidity of the procedure. In fact, all providers of emergency care (including hospitalists) should be familiar with IOVA because in certain situations it may be the only available means of obtaining vascular access. It should be noted that since the last edition of this textbook was published (2003), this procedure has been moved from the Pediatrics section to the Hospitalist section; again, many hospitalists use IOVA in adults more often than in children. To learn the procedure or to maintain skills for IOVA, clinicians can practice on cadavers, raw chicken drumsticks, swine ribs, or piglet tibias. Mannequins are also available for practice from the manufacturers of the special IOVA kits.

The proximal tibia (Fig. 198-2), just below the growth plate, is the preferred site for IOVA for children younger than 5 years of age. At this level, the tibial tuberosity is a broad, flat surface close to the skin and there are few intervening muscles, nerves, and blood vessels; therefore, bony landmarks are easily recognized.

Recently, IOVA kits with either a battery-operated drill (EZ-IO; Vidacare, Dallas) or a spring-loaded needle gun (Bone Injection Gun [BIG]; WaisMed, Houston) have been demonstrated to be effective for use in the proximal humerus; having vascular access above the diaphragm during CPR is considered important by many clinicians. The distal tibia (Fig. 198-3), just above the medial malleolus, the lateral or medial malleolus, the distal radius, ulna, or femur (Fig. 198-4), the anterior-superior iliac spine, and the sternum are alternate sites for IOVA. Whereas the distal tibia is a good choice because the bone and tissues are thin, the distal femur is covered with muscles and fat, often making palpation of bony landmarks difficult. The distal femur should probably be reserved for those cases in which other sites cannot be used. The sternum and ilium are seldom used in children because the width of the marrow

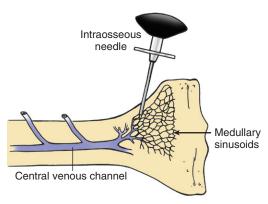

Figure 198-1 Intramedullary venous system. With intraosseous venous access, the marrow cavity functions as a "vein" that will not collapse.

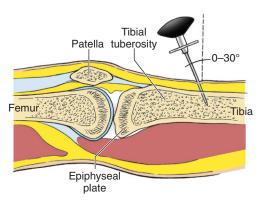

Figure 198-2 Proximal tibial needle insertion.

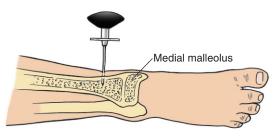

Figure 198-3 Distal tibial needle insertion.

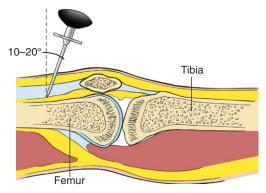

Figure 198-4 Distal femoral needle insertion.

space is inadequate if younger than 3 years of age, and insertion may be technically difficult and dangerous. In children and adults, the sternal site carries a risk of mediastinal puncture.

#### **INDICATIONS**

- As an alternative to a central line for short-term infusions
- Any emergency condition that requires immediate vascular access (IOVA can often be achieved in 30 to 60 seconds)
- When IV access cannot be achieved (e.g., small veins, venofibrosis, edema, obesity; also for regional anesthesia when the distal extremity is injured)

**NOTE:** When a large-volume infusion is needed very rapidly, bilateral IOVA may be necessary as well as the use of a pressure infusor bag, an infusion pump, a large syringe, or forceful manual pressure.

 IOVA is preferred over the endotracheal route for medication administration (certain fluids or medications can be given *only* by IV or IOVA route, and *not* through an endotracheal tube; e.g., blood, sodium bicarbonate, dextrose)

#### **CONTRAINDICATIONS**

Contraindications to IOVA are few and are all relative, especially because this is a very temporary, and occasionally a life-saving, procedure. However, the risks and benefits of the procedure should be considered.

- Ipsilateral fracture or crush injury of an extremity (increases the risk of subcutaneous extravasation, so another extremity should be used)
- Previous orthopedic procedure near the selected insertion site
- Previous IOVA attempts in the same bone (even if IOVA was obtained, fluid would leak out of the previously attempted site)
- Infection at the selected insertion site
- Inability to locate landmarks (e.g., excessive tissue over the insertion site)
- Brittle bones (e.g., osteogenesis imperfecta or anything increasing risk of fracture)

#### **EOUIPMENT**

- Disposable rigid needle, 16- to 20-gauge, preferably with stylet and designed as an intraosseous needle. Options include kits with a small, portable battery-powered drill, intraosseous needle, and integrated stylet that doubles as a drill bit (EZ-IO AD for patients ≥40 kg, EZ-IO PD for patients >6 kg, <40 kg; Fig. 198-5A) or a spring-loaded needle, disposable bone injection gun (BIG Adult or BIG Pedi; Fig. 198-5B), or a disposable needle with a built-in handle (Fig. 198-5C). If none of these is available, spinal needles (with a stylet) or bone marrow aspiration needles (e.g., Jamshidi) have been used to perform this procedure in children for years.</p>
- Sterile latex gloves.
- · Goggles.
- Sterile drapes.
- Antiseptic solution (povidone-iodine, chlorhexidine, or alcohol).
- Two 10-mL syringes for aspirating medullary contents and flushing with normal saline.
- 2 × 2 gauze pads.
- 4 × 4 gauze pads.
- Tape.
- IV solution (isotonic crystalloid or colloid), tubing, and pressure infusor bag (can use a blood pressure cuff) or infusion pump (large syringes can also be used for boluses).
- Extremity or torso restraints for the uncooperative patient.
- Plastic or Styrofoam cup.

**Figure 198-5 A,** Intraosseous needle, drill bit stylet, battery-operated drill (EZ-IO). **B,** Spring-loaded needle gun (Bone Injection Gun [BIG]). **C,** Intraosseous vascular access needle with handle. (**A,** Courtesy of Vidacare, Dallas, TX. **B,** Courtesy of WaisMed, Houston, TX. **C,** Courtesy of Cook Critical Care, Bloomington, Ind.)

- In the alert patient, 2% lidocaine without preservatives (cardiac lidocaine) without epinephrine and a 10-mL syringe
- In the alert patient (optional), 1% or 2% lidocaine for local anesthetic and a 3- or 5-mL syringe with a 25- or 27-gauge, %-inch (1.6-cm) needle.

#### PREPROCEDURE PATIENT EDUCATION

In most cases, IOVA is performed emergently. When time allows, the indications should be documented and explained to the parent or other relative, if present. If performed electively, the indications, alternatives, benefits, and risks should be explained to the patient or parent, and signed informed consent should be obtained.

#### **TECHNIQUE**

**NOTE:** The following techniques and angles are for the standard IOVA needle. The battery-powered drill or bone injection gun is used most often at the proximal tibial site in adults and children and at the proximal humeral site in adults. The battery-powered drill is also used at the distal tibial site. The battery-powered drill and bone injection gun should be held perpendicular to the bone during insertion of the needle.

The operator should be familiar with the particular device available for IOVA and review the device specific protocol prior to use because the application of each device may vary slightly.

- 1. If an extremity is the chosen site, place a small sandbag beneath it. An assistant or restraint may be useful for an infant or a confused patient. If an extremity is the desired site, everyone should avoid placing a hand behind the extremity in case of through-and-through bone penetration.
- 2. Prepare the skin with antiseptic solution and drape the area. Follow universal blood and body fluid precautions.
- Administer local anesthetic down to the periosteum (this is optional; it may not be necessary for patients with an altered mental status).
- 4. To avoid through-and-through bony penetration, hold your index finger approximately 1 cm from the needle tip and avoid pushing past this mark. This step is not necessary if using a kit with a battery-operated drill or spring-loaded bone injection gun.

- 5. Perform the procedure according to the selected insertion site:
  - Proximal tibia

Palpate the tibial tuberosity with your finger (it is the most prominent point on the tibia, noted immediately distal to the patella). In children, select a site approximately one or two fingerbreadths (1 to 2 cm) below the tibial tuberosity and one or two fingerbreadths medial to it. This should place the IOVA on the flat surface of the proximal, anteromedial tibia. In adults, the IOVA site can be found by first moving one or two fingerbreadths medial to the tibial tuberosity, and then moving one or two fingerbreadths above or below this location.

Grasp the medial aspect of the tibia with the thumb and fingers of your nondominant hand to secure it.

Using your dominant hand, with the stylet in place, insert the IOVA needle with a gentle, but firm, boring or screwing motion at an angle of 60 tp 80 degrees to the proximal skin (which is a 10- to 30-degree angle to verticle; see Fig. 198-2). To avoid bending the needle, twist it rather than pushing it. If the needle is threaded, it should be twisted clockwise to screw it into the bone. The needle should be pointed caudad, in the direction of the long axis of the bone, away from the epiphysis. The IOVA needle kits with either a battery-powered drill or bone injection gun can be used in the same location, but should be held perpendicular to the bone. Again, every effort should be made to avoid the epiphysis.

Head of humerus

Palpate the anterior aspect of the head of humerus.

Grasp the humerus in the nondominant hand to secure it. Make sure your nondominant hand is well below the insertion site in case there is through-and-through needle penetration of the bone.

Using your dominant hand, the IOVA needle kits with either a battery-powered drill or bone injection gun should be held perpendicular to the bone.

The needle should then be inserted. Care should be taken when disconnecting the needle from the drill or injection gun to avoid dislodging the needle.

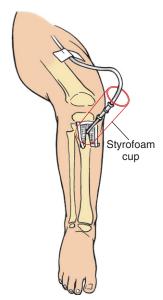

• Distal tibia

Insert the IOVA needle into the distal medial tibia at the broad, flat area proximal to the medial malleolus and posterior to the saphenous vein. It should be inserted at an angle perpendicular to the skin (see Fig. 198-3). Again, the IOVA needle kits with a battery-powered drill can be used at this location and directed at the same angle.

Distal femur (EZ-IO not indicated in this location)
 Insert the needle 2 to 3 cm above the epicondyles in the anterior midline.

Direct the needle cephalad at an angle of 70 to 80 degrees to distal skin (10 to 20 degrees from the vertical; see Fig. 198-4).

- 6. Placement in the marrow space is confirmed by the following:
  - There is a decrease in resistance (it "gives") as the needle passes through the cortex into the softer medulla. The skinto-cortex distance is rarely more than 1 cm in infants and children.
  - The needle should stand upright without support when the stylet is removed.
  - Marrow should be easily aspirated into a syringe, followed by blood (note: marrow or blood may not be aspirated in every case).
  - Fluids should infuse easily without extravasation.
- 7. Radiographs can be used to confirm needle position if time and the clinical situation permits (*optional*).
- Flush the needle with saline solution (heparin is optional). Check for swelling (extravasation of fluid) around the needle or behind the extremity. If the test injection is unsuccessful

**Figure 198-6** Completed intraosseous vascular access with cup protector.

(i.e., extravasation is noted), the IOVA should be removed and another site chosen. If an extremity is to be used, it should be another one. If the same extremity is used, fluid will leak through the prior hole in the cortex, possibly causing damage by extravasation.

**NOTE:** For the alert patient, 2% lidocaine without preservatives and without epinephrine (i.e., cardiac lidocaine, observing same contraindications and precautions as cardiac lidocaine; up to 5 mL in adults, less for children, adjusted for weight) can be infused very slowly (slow enough to prevent it being sent directly into the central circulation) to decrease the discomfort associated with later infusions. Lidocaine infused in this manner goes directly into the marrow to provide analgesia, prior to the saline flush.

9. If the IOVA has a flange, it should be taped down. A sterile 2 × 2 gauze pad cut to fit around the needle should also be taped down as a dressing. Next, place a cup (Styrofoam or plastic, with the bottom removed) over the IOVA site and firmly secure it with tape (Fig. 198-6).

**NOTE:** The cup offers additional protection for the IOVA in the case of inadvertent extremity movement.

- 10. Attach the pressure bag infusor or an infusion pump to the IV bag, and tape the IV tubing in place. The tubing should be taped both to the patient (to avoid putting tension on the IOVA) and to the IV line (to avoid it being disconnected). Pressure bag infusors, infusion pumps, or forceful manual pressure can be used to administer large volumes. Large fluid boluses can also be given with a large syringe, either through a medication port in the IV line or through a saline lock attached to the IOVA. When giving large volumes under pressure, care should be taken to avoid air embolism.
- Restrain the limb with soft restraints to avoid inadvertent movement.
- 12. Monitor the infusion site for evidence of needle displacement or extravasation. Needle displacement can result in severe complications from extravasation (e.g., compartment syndrome, tissue necrosis). Establish peripheral IV access within 24 to 48 hours after IOVA placement, and then remove the IOVA.

#### Removal

- 1. Rotate the needle slightly to loosen its seal. (If inserted by portable, battery-powered drill, rotate the needle clockwise.) Withdraw the needle with a firm, quick motion.
- 2. Place a sterile pressure pad over the puncture site; apply firm pressure for 5 minutes to prevent hematoma formation. Next, apply a sterile dressing to the extremity. Do not constrict the extremity with the dressing.

#### POSTPROCEDURE MANAGEMENT

After IOVA removal, the dressing must be changed daily. Dressings may be discontinued after 48 hours. The patient, his or her family, and the nursing staff should be taught to monitor for signs of infection and other possible complications.

#### **COMPLICATIONS**

- The most common complication is unsuccessful placement. This
  was previously due to the technical difficulty of the procedure;
  however, IOVA systems that include a battery-powered drill or
  spring-loaded needle gun have markedly increased the success
  rate. Technical failure is now most commonly due to a lack of
  familiarity with the equipment or the landmarks, or an improper
  technique.
- Clotting of marrow in the needle or displacement of the needle may lead to loss of vascular access.
- Subcutaneous, or occasionally subperiosteal, infiltration of fluid or leakage from the puncture site is common. This is especially common with use of pressure infusor bags, infusion pumps, or manual pressure, or with long-term use of intraosseous infusion. Extravasated crystalloid is usually not a problem, but solutions containing calcium chloride, epinephrine, or sodium bicarbonate (or other potentially cytotoxic agents) should be stopped or slowed to minimize extravasation. Muscle or tendon compartment syndromes from excessive fluid extravasation are a possibility.
- Slow infusion rates may be due to a small, fibrotic marrow cavity (rare). Initially, flow rates may be slow because the needle is plugged by marrow contents. Flushing the needle with 5 to 10 mL of saline often clears the needle.
- No lasting effects have been noted in bone, growth plate, or marrow elements after IOVA. The needle is directed away from the growth plate, or the insertion site is distal enough to avoid inadvertent injury to this structure. After successful placement, a small defect is created in the cortex that is visible as a small radiolucent area on radiographs. It should resolve in 30 to 40 days. In one case report, tibial fractures were seen after unsuccessful IOVA attempts, but these are very rare.
- Localized cellulitis or a subcutaneous abscess may be observed in less than 1% of cases. In most studies, the incidence of osteomyelitis was less than 1%. Infections were usually associated with prolonged catheter placement, placement in bacteremic patients, or use of hypertonic infusions.
- Hematomas are most likely caused by local trauma from needle insertion.
- Pain is possible with insertion and when intramedullary pressure is increased during infusion. It is generally not a problem with slow infusions or in the unconscious patient. Slowing the infusion rate in the conscious patient may relieve symptoms.
- A theoretical complication is creation of a bone embolus when a needle without a stylet is used. No documented cases of a bone embolism have been reported. A fat embolism has been reported from tibial infusion in adults but not in children, probably because the marrow in children is relatively fat free.
- Bone marrow elements (immature blood cells, including blasts) have been observed in venous blood sampled proximal to IOVA

infusion sites. Before more invasive diagnostic measures are undertaken, a repeat complete blood count with differential should be performed, preferably from the more permanent replacement IV site on another extremity.

- With sternal puncture, death has occurred from mediastinitis, hydrothorax, or injury to the heart or great vessels. This is avoidable if other sites are used rather than the sternum.
- Through-and-through placement of the needle can occur. Placing your index finger approximately 1 cm from the needle tip can prevent advancement of the needle through the opposite side of the bone. Your finger will prevent pushing too deep. (Some intraosseous needles have a preset depth indicator on the shaft.)

# CRICOTHYROID CATHETER INSERTION, CRICOTHYROIDOTOMY, AND TRACHEOSTOMY

David Roden

Establishing an airway is crucial to a patient's survival and is of paramount importance in an emergency. If endotracheal or nasotracheal intubation is impossible, several techniques can be used to establish a surgical airway. Cricothyroid catheter insertion (also known as percutaneous transtracheal jet ventilation) and cricothyroidotomy are usually performed in emergencies, whereas tracheostomy is usually performed under controlled conditions.

Cricothyroid catheter insertion is the least invasive procedure, requires the least surgical skill, does not require an assistant, and is the quickest technique. It also has the lowest risk of complications, such as bleeding, glottic stenosis, subglottic stenosis, or tracheal ulceration. This technique provides a temporary airway to preserve oxygenation until a larger airway can be established. (If used with intermittent jet of pressurized 100% oxygen at 50 pounds per square inch [psi], adequate ventilation is also provided; exhalation occurs passively due to secondary recoil of the lungs and chest wall.) Emergency personnel also use cricothyroidotomy as a lifesaving maneuver. One advantage of cricothyroid catheter insertion and cricothyroidotomy is the speed with which they can be performed. They also do not require a lot of equipment and result in less scarring than tracheosotomy. Because the airway is most superficial at the level of the cricothyroid membrane and anatomic landmarks are easily identifiable, this location is ideal for the clinician to create an airway. Serious bleeding and perforation of other structures can also usually be avoided at this site.

Tracheostomy is the most complicated surgical airway procedure and requires the most equipment. It is performed at a level two tracheal rings below the cricothyroid membrane. This site is farther away from the larynx, so the incidence of laryngeal injury is much lower, especially if the opening is maintained for a prolonged time. Dissection is more complicated because the trachea is located deeper than the cricothyroid membrane, so the clinician must be familiar with local anatomy to minimize risk. Tracheostomy is associated with two to five times the complication rate when performed as an emergency procedure; therefore, it is rarely performed except under controlled circumstances in the operating room. In addition, the complete procedure usually takes too long to be useful for emergency airway management and can be difficult for the untrained clinician to perform. The only situation in which emergency tracheostomy is preferred is when the specific location of the injury or disease (e.g., subglottic tumor, thyroid cartilage fracture) precludes alternatives.

#### **CRICOTHYROID CATHETER INSERTION**

#### **Indications**

- Temporary need for an airway
- Upper airway obstruction, usually resulting from foreign body, infection, neoplasm, edema, or trauma
- Preferred technique for establishing emergency airway in pediatric age group if endotracheal intubation fails

#### **Contraindications**

- There is an intact nonsurgical airway.
- Subglottic obstruction exists.
- Thyroid cartilage fracture or damage to larynx or cricoid cartilage: anterior neck trauma may be a contraindication if these structures are possibly damaged. In these situations, tracheostomy is preferred.
- Complete airway obstruction is a contraindication for jet ventilation (results in barotrauma or auto-positive end-expiratory pressure [auto-PEEP]; a patent airway is needed for outflow of gas with expiration).

#### **Equipment**

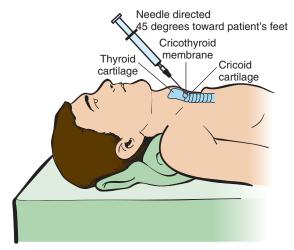

- Goggles or eye protection
- Mask, cap, gown, and sterile gloves
- 12-, 14- or 16-gauge, 2- to 3-inch over-the-needle catheter (angiocatheter)
- 5- or 10-mL syringe
- Lidocaine 1% with epinephrine in 10-mL syringe with 22-gauge, %-inch needle
- Skin-sterilizing supplies such as povidine-iodine (if time allows)
- Adhesive tape
- Umbilical tape, 2-0 monofilament nylon suture and needle holder or commercially available endotracheal tube connecter
- High-pressure oxygen supply (30 to 60 psi) with a pressure gauge and a pressure-regulating valve (if high-pressure oxygen is not available, a 3-mL syringe barrel [without a plunger] can be attached to the catheter; a standard endotracheal tube connector can then be used to attach the catheter to a bag-mask-valve [Ambu bag] device)
- Hand-operated valve connected inline to tubing and catheter
- Alternate: an oxygen regulator and manual trigger

#### **Preprocedure Patient Preparation**

No patient education is needed in the emergency setting. Documentation should be made in the patient's chart that informed consent was obtained if time allows. If time does not allow, an explanation of the emergent need for this procedure should be documented.

#### **Procedure**

- Position the patient in the supine position with the chin directly midline and maximally extended (if no cervical spine trauma). If a cervical fracture is suspected, the neck should remain immobilized in a neutral position.
- 2. Clean the neck with povidone–iodine or other antiseptic solution.
- 3. Observe universal blood and body fluid precautions. Observe sterile technique (cap, gloves, mask, gown, and drapes).
- 4. Use the nondominant hand to identify the cricothyroid membrane, which is located immediately caudal to the prominent thyroid cartilage (Adam's apple). It is the first small depression or indentation inferior to the hard thyroid cartilage, between the cricoid and thyroid cartilages. It should be easily palpable, even in obese individuals.
- 5. If the patient is awake, and time allows, infiltrate lidocaine as a wheal and then down to the membrane in the desired location using a 10-mL syringe with a 22-gauge needle.
- 6. With the nondominant hand, immobilize the thyroid cartilage and hold the skin taut over the cricothyroid membrane.
- 7. Direct the catheter-over-needle attached to the syringe downward in the midline and caudally at an angle of 45 degrees (Fig. 199-1). Inserting the catheter-over-needle in the inferior aspect of the cricothyroid membrane minimizes risk of injury to the cricothyroid arteries. Aspirate with the syringe during insertion. When air is obtained with aspiration, the needle has entered the trachea.
- 8. Advance the catheter over the needle, withdraw the needle and syringe, and attach the distal end of the high-pressure oxygen tubing to the catheter.
- 9. Open the hand-operated release valve to deliver pressurized oxygen to the trachea. As soon as the chest rises, assume that the patient has been oxygenated; the valve should then be closed. Open the valve, watch the chest rise, and close the valve—in a rhythmic pattern—to approximate actual breathing. Adjust the overall pressure level to allow adequate lung expansion.

**Figure 199-1** Over-the-needle catheter is inserted through cricothyroid membrane with syringe attached. The clinician should aspirate while inserting the needle.

- 10. Most upper airway obstructions are incomplete and allow some ventilation to occur with forced exhalations. (If the chest remains inflated during the exhalation phase, a complete proximal airway obstruction may be present. In this case, a second large-bore over-the-needle catheter can be inserted next to the original catheter. If the chest still remains distended, cricothyroidotomy should be performed.)
- 11. The oxygen line should be taped to the catheter. Next, secure the catheter and oxygen tubing by placing a stitch through the skin near the catheter (after infiltration of lidocaine in the conscious patient), wrapping one end of the suture around the catheter several times and tying it to the base of the other end of the suture near the skin. The other end of the suture can then be wrapped several times around the oxygen tubing and tied to the original end of the suture near the skin. Alternatively, a piece of umbilical tape or adhesive tape can be wrapped around the patient's neck, the catheter hub, and the oxygen tubing. Or a commercially available endotracheal tube holder can be wrapped around the patient's neck and connected to the oxygen tubing; the catheter will still have to be secured with suture or by being taped to the tubing and skin.
- Obtain an arterial blood gas. Pulse oximetry, blood pressure, and telemetry should be monitored.

#### Complications

- Inadequate ventilation or hypoxia (often due to catheter kinking as it travels through the tissue; use of commercially available kink-resistant catheters minimizes this risk)
- Barotrauma (can cause pneumothorax, pneumomediastinum, or pneumopericardium; auto-PEEP can result in decreased mean arterial pressure)
- Subcutaneous emphysema
- Aspiration (pressurized airflow may minimize risk of aspiration; however, make sure to suction upper airway before discontinuing cricothyroid catheter)

**NOTE:** Cricothyroid catheter insertion through the cricothyroid membrane may maintain spontaneous respirations for a few minutes. This is the procedure of choice for children under 12 years old because the cricothyroid membrane is small. If this maneuver is inadequate, formal tracheostomy is indicated.

#### **CRICOTHYROIDOTOMY**

#### **Indications**

- Upper airway obstruction, usually resulting from foreign body, infection, neoplasm, edema, or trauma
- When endotracheal or nasotracheal intubation has failed, is contraindicated, or is unavailable
- Patient with a cervical spine fracture who cannot extend neck for intubation
- Prior cricothyroidotomy catheter insertion complicated by carbon dioxide retention or air entrapment

#### **Contraindications**

- Intact nonsurgical airway
- Subglottic obstruction
- Thyroid cartilage fracture or damage to larynx or cricoid cartilage (anterior neck trauma may be contraindication if these structures are possibly damaged); in these situations, trachestomy preferred
- Patient younger than 8 years old (cricothyroid catheter insertion or needle cricothyroidotomy is the preferred procedure for this age group)
- Relative contraindications: a coagulopathy, massive neck swelling or hematoma, or previously prolonged endotracheal intubation (tracheostomy or conversion to tracheostomy may be preferred)

#### **Equipment**

- Goggles or eye protection
- No. 15 scalpel blade with handle
- Size 4 to 6 endotracheal tubes or size 4 to 6 Shiley cuffed tracheostomy tubes
- Adhesive tape
- Umbilical tape and 2-0 monofilament nylon suture and needle holder (if a tracheostomy tube is used)
- Sterile 4 × 4–inch gauze sponges
- Self-refilling bag-valve-mask unit (Ambu bag) with tubing and oxygen source
- Suction and suction catheters

If time allows

- Povidone–iodine (Betadine) or other antiseptic skin preparation
- Mask, cap, gown, and sterile gloves
- Sterile fenestrated drape
- Lidocaine 1% with epinephrine in 10-mL syringe with 22-gauge, %-inch needle

If a tracheostomy tray is available:

- Hemostat clamps (2)
- Kelly clamps (2)
- Tracheal dilator (Trousseau)
- Curved scissors

#### **Preprocedure Patient Preparation**

No patient education is needed in the emergency setting. Documentation should be made in the patient's chart that informed consent was obtained, if time allows. If time does not allow, an explanation of the emergent need for this procedure should be documented.

#### **Technique**

**NOTE:** In extremely urgent situations, the goal is to save a life, so some concerns about sterile technique should be postponed.

- Position the patient in the supine position with the chin directly midline and maximally extended (if no cervical spine trauma). If a cervical fracture is suspected, the neck should remain immobilized in a neutral position.
- 2. Clean the neck with povidone-iodine or other antiseptic solution
- 3. Observe universal blood and body fluid precautions. Observe sterile technique (cap, gloves, gown, mask, and drapes).
- 4. Use the nondominant hand to identify the cricothyroid membrane, which is located immediately caudal to the prominent thyroid cartilage (Adam's apple). It is the first small depression or indentation inferior to the hard thyroid cartilage, between the cricoid and thyroid cartilages. It should be easily palpable, even in obese individuals.

**NOTE:** The cricothyroid membrane averages 9 mm in the cephalad-caudad dimension and 30 mm in the left-to-right dimension in adults. It should be easily palpable and accessible.

- 5. If the patient is awake, and time allows, use the 10-mL syringe with the 22-gauge needle to infiltrate lidocaine in a large subcutaneous wheal encompassing the future vertical skin incision. Next, infuse lidocaine in a transverse line across the membrane.
- 6. With the nondominant hand, immobilize the thyroid cartilage and hold the skin taut over the cricothyroid membrane. Using the no. 15 blade, make a 3-cm vertical (longitudinal) skin incision centered over the cricothyroid membrane (Fig. 199-2).

**NOTE:** Certain authorities recommend a transverse skin incision. Making a longitudinal incision slows down the procedure and requires repositioning after the skin incision; however, if

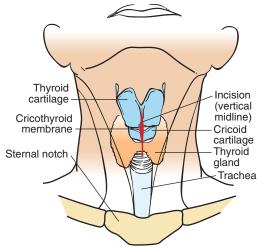

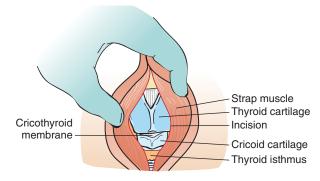

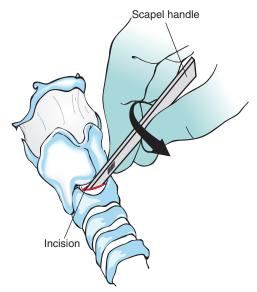

Figure 199-2 Neck extended, with cricothyroid membrane identified.

the transverse skin incision is accidentally extended too far laterally (e.g., when the procedure is performed under duress), the anterior jugular veins may be injured. If a patient has a suspected laryngeal injury, the longitudinal incision is indicated in the event it needs to be extended inferiorly to perform an emergency high tracheostomy.

- 7. Use the finger and thumb of the nondominant hand to retract the incision edges laterally (Fig. 199-3).
- 8. Divide the neck fascia and strap muscles vertically in the midline with the scalpel until the thyroid and cricoid cartilages are encountered. In general, cartilage provides considerable resistance to the scalpel, so these structures are not easily injured.
- 9. Retracting soft tissue structures laterally, locate the cricothyroid membrane by palpation with the dominant hand and use the scalpel to create a 1- to 2-cm transverse incision centered in the midline, immediately above the cricoid cartilage. Be aware that at this point any respiratory effort by the patient will expel sputum, blood, and air into the wound. A low incision should avoid vocal cord injury and the cricothyroid arteries. The posterior aspect of the cricoid cartilage should be avoided, but even if the knife goes too deep, the cricoid cartilage should stop the progression of the knife.
- 10. Reverse the scalpel, placing the handle into the cricothyroidotomy incision horizontally. Rotate the handle 90 degrees to open the incision (Fig. 199-4).

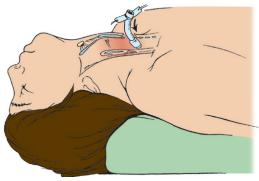

**Figure 199-3** After a vertical skin incision, soft tissue structures are retracted laterally with the nondominant hand.

**Figure 199-4** Scalpel handle inserted into incision and twisted vertically to open it.

If a tracheostomy tray is available, an alternative to Step 10 is as follows:

- 10. After using the scalpel to make a transverse midline incision in the cricothyroid membrane, insert a hemostat or Kelly clamp with the points downward into the trachea and spread laterally. A rush of air indicates patency of the airway. Alternatively, a tracheal dilator can extend the cricothyroid membrane incision laterally approximately 1 cm on each side of the midline. From here, continue with the remainder of the steps in the technique.
- 11. Use the nondominant hand to place the largest possible endotracheal tube or, preferably, tracheostomy tube into the incision. The scalpel handle can be used as both a retractor and a guide. Direct the tube tip toward the patient's feet and attempt to visualize its insertion into the trachea (Fig. 199-5). Do not release the hold on the tracheostomy or endotracheal tube until it is secured.
- 12. Connect the bag-valve-mask unit (Ambu bag) to the tube and ventilate with 100% oxygen. Check for bilateral breath sounds to ensure that the tube is properly placed above the carina.
- 13. Inflate the cuff with enough air to stop any audible air leaks.
- 14. Secure the tube and then apply a dressing. If an endotracheal tube is being used, secure the tube in place using tape. If a tracheostomy tube is being used, secure the tube with umbilical tape around the patient's neck. Place four interrupted sutures with 2-0 nylon through the tube's flange to secure it to the skin.

**Figure 199-5** Tube is inserted into the incision. Scalpel handle is still in cricothyroid membrane (not shown for clarity).

- 15. Suction the trachea.
- 16. Obtain an arterial blood gas and a chest radiograph. The radiograph should demonstrate tube position above the carina and should ensure the absence of an iatrogenic pneumothorax.

#### Complications

- Intraoperative and postoperative bleeding (direct pressure will usually stop bleeding after the airway is established)
- Improper tube placement with asphyxia
- Tube displacement or obstruction with subsequent hypoxia or death
- Subcutaneous or mediastinal emphysema
- Laryngeal or vocal cord injury (especially if tracheostomy tube is larger than cricothyroid membrane)
- Voice changes (e.g., hoarseness)
- Infection
- Subglottic stenosis
- · Perforated esophagus

To prevent subcutaneous or mediastinal emphysema or infection, the skin incision should not be closed around the tube. If the cricothyroidotomy is only necessary for 48 to 72 hours (e.g., resolving infection, angioedema of tongue), the patient can be decannulated without converting to a tracheostomy. If a longer period of intubation is required (see the "Tracheostomy" section for a discussion of the controversies of timing), the procedure should be revised to a tracheostomy to prevent subglottic stenosis.

#### **Postprocedure Patient Education**

If prolonged airway management is needed, convert the cricothyroidotomy to a tracheostomy and provide the appropriate patient education. If the cricothyroidotomy is able to be removed within 48 to 72 hours, give the patient instructions for the routine care of a skin laceration. The patient should be aware that the fistula will close spontaneously. He or she should have a follow-up appointment within a week and should call or go to the emergency room for signs of hemorrhage, infection, airway distress, or subcutaneous emphysema.

#### **TRACHEOSTOMY**

#### **Indications**

- Chronic ventilatory failure (most common indication)
- Upper airway obstruction usually resulting from infection, neoplasm, edema, or trauma; also obstructive sleep apnea and bilateral vocal cord paralysis
- Anticipated prolonged endotracheal intubation
- Facial, tracheal, or other head and neck trauma or surgery with compromised airway
- Fractured larynx or subglottic obstruction (cricothyroidotomy contraindicated)
- Chronic impaired pulmonary toilet
- Management of chronic aspiration
- Unstable cervical spine

NOTE: Management of bronchial secretions is much easier with a tracheostomy tube than with an endotracheal tube. Risk of endotracheal tube complications (e.g., tube displacement, sinusitis, tube kinking) is also reduced with conversion to a tracheostomy. However, the recommended timing for conversion has been debated extensively. Supporters for early conversion (7 days) suggest that laryngeal complication rates and patient comfort are improved with early conversion. Advocates for delayed placement of tracheostomy (14 to 21 days) state that unnecessary procedures will be avoided, reducing local wound and other surgical complications. Most experts have adopted an intermediate approach that is individualized to the

patient. If the patient is expected to be intubated for considerably longer than 7 days, a tracheostomy is placed early. However, if the patient's course cannot be predicted, the conversion can be delayed until prolonged need becomes evident.

#### **Contraindications**

- · Lack of familiarity with the procedure
- Known preexisting severe tracheal disease or trauma
- Uncontrolled coagulopathy

**EDITOR'S NOTE:** Cricothyroidotomy is the procedure of choice when an invasive approach to the airway is needed.

#### **Equipment**

- Povidone–iodine or other antiseptic solution
- 1 package of 4 × 4-inch sterile gauze sponges
- Sterile gown and gloves
- Sterile fenestrated drape
- Cap, mask, and eye protection
- Electrocautery machine
- 10- and 50-mL syringes
- 22- and 25-gauge, %-inch needles
- No. 15 scalpel blade with handle
- Mosquito hemostats (4)
- Kelly clamps (2)
- Subcutaneous or Army-Navy retractors (2)
- Trousseau (tracheal) dilator
- Allis clamps (2)
- Tracheal hook
- Sizes 4, 6, and 8 cuffed Shiley tracheotomy tubes
- Needle holder
- Umbilical tape and 2-0 monofilament nylon suture
- Suction apparatus, tubing, and catheters
- Ventilation equipment: bag-valve-mask unit (Ambu bag) with tubing and 100% oxygen available
- 3-0 Dexon or chromic absorbable suture on a cutting needle

#### **Preprocedure Patient Preparation**

Education of the patient and family should include the indication for tracheostomy and possible complications. Benefits of the procedure, as well as the risks of not performing it, should be explained to the patient and family. If there are alternatives to this procedure, they should be explained. Informed consent should be obtained in nonemergent situations.

#### **Technique**

- Tracheostomy can be performed under local anesthesia on a spontaneously breathing patient, or under general anesthesia on a previously intubated patient. Exercise caution in administering sedation to a nonintubated patient with a compromised airway.
- 2. Position the patient in the supine position with a roll under the shoulders and, if there is no cervical spine trauma, with the neck maximally extended (Fig. 199-6). Placement of an endotracheal tube before elective tracheostomy (or leaving an existing tube) allows for better airway control and minimizes complications, especially in children. The anesthetist should stand above the patient's head for better access to the endotracheal tube, if present.
- Prep the neck with povidone-iodine or other antiseptic solution from sternum to chin, and laterally to the sternocleidomastoid muscles. Apply the fenestrated drape.

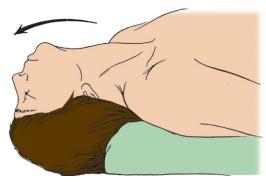

Figure 199-6 Patient is positioned for tracheostomy.

- Check the tracheostomy tube cuff for leaks prior to making the incision. A second tube should be tested and available, if possible.
- Palpate landmarks: the sternal notch, cricoid cartilage, and inferior border of the thyroid cartilage. Outline a horizontal incision two fingerbreadths above the sternal notch, centered in the midline over the trachea.
- 6. For conscious patients, inject lidocaine subcutaneously around the intended incision site. Lidocaine can then be injected down to the anterior tracheal wall beneath the incision.
- 7. Using the scalpel, make a horizontal incision through skin and subcutaneous tissue down to the strap muscles (Fig. 199-7). Alternatively, once the skin has been incised, electrocautery can be used to divide the subcutaneous tissue horizontally, deepening the incision until the strap muscles are encountered.
- 8. Clamp the subcutaneous tissue with Allis clamps and retract superiorly and inferiorly. Next, incise the fascia vertically in the midline, in the raphe between the strap muscles. Incise down to the pretracheal fascia (Fig. 199-8).

**NOTE:** Often the strap muscles are fused in the midline and covered by a network of troublesome veins. Attempts should be made to cauterize or ligate these veins.

- 9. Place retractor(s) beneath the strap muscles and apply traction laterally. Incise the pretracheal fascia to expose the thyroid isthmus and tracheal rings (Fig. 199-9).
- 10. Retract the thyroid isthmus superiorly, if possible, to increase visibility. If exposure is inadequate, horizontally incise the fascia immediately caudal to the lower border of the cricoid cartilage but do not enter the trachea. Insert a hemostat through this

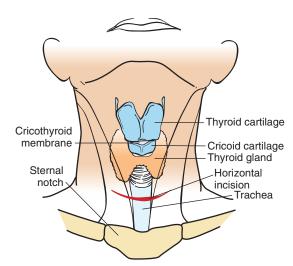

Figure 199-7 Horizontal incision is made through the skin.

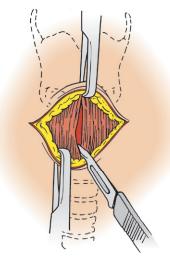

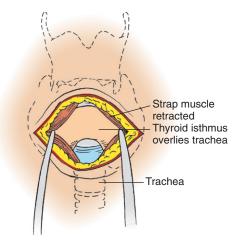

Figure 199-8 Fascia and strap muscles are divided in the midline.

incision pointed toward the patient's feet, parallel to the trachea. Bluntly dissect the thyroid isthmus off the anterior wall of the trachea. After an additional attempt at superior or inferior retraction, if visibility is still inadequate, it may be necessary to divide the thyroid isthmus with clamps and suture the ligated edges (Fig. 199-10). A 3-0 chromic suture is used to oversew each edge for hemostasis.

**NOTE:** It is important to remain in the midline with this procedure to minimize complications, especially in children.

- 11. If unsure that the object visualized is the trachea, aspirate for air with a small-bore needle to confirm before proceeding. Next, place a tracheal hook beneath the cricoid cartilage and elevate it toward the surgeon and toward the patient's head. If using local anesthesia, 1 to 2 mL should be injected beneath the second tracheal ring into the tracheal lumen. This should stimulate the nonanesthetized patient to cough.
- 12. Make a transverse incision between the second and third rings (Fig. 199-11). Be prepared for a spurt of blood, air, or sputum, and have suction ready. Do not use electrocautery to incise the trachea because there is a the risk of airway fire. Take care not to puncture the endotracheal tube cuff if present or the posterior wall of the trachea. (Alternatively, some clinicians make an inverted U-shaped incision. Others make a square "window" incision and remove the anterior portion of the second and third tracheal rings. A midline vertical incision through the

**Figure 199-9** Strap muscles are retracted laterally to expose the thyroid isthmus.

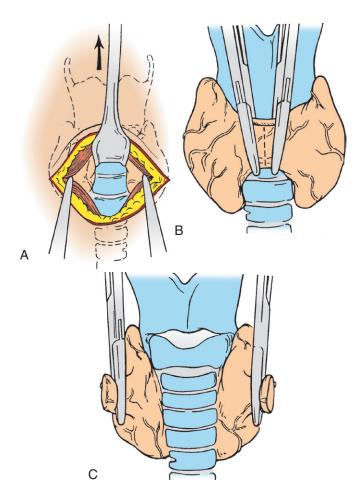

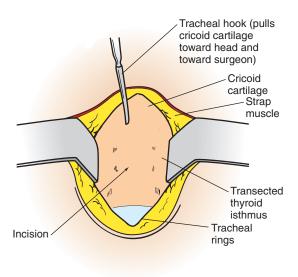

Figure 199-10  $\,$  **A,** Thyroid isthmus is retracted. If exposure is inadequate, the thyroid isthmus should be clamped (B) and divided (C).

second, third, and fourth tracheal rings is the incision of choice for an emergency tracheostomy.)

- 13. Insert a Trousseau dilator into the trachea and dilate laterally (Fig. 199-12).
- 14. Withdraw the endotracheal tube (if one is in place) until the tip is just above the tracheostomy. Under direct visualization, insert the appropriately sized tracheostomy tube through the dilated incision, with the tube tip directed downward (Fig. 199-13). Most adults will fit a size 8 Shiley tube. Inflate the tracheostomy tube cuff. Suction through the tube with a flexible suction catheter. Bronchoscopy can be performed at this point to confirm proper tracheostomy tube placement.
- 15. Attach the tube to the bag-valve-mask (Ambu bag) device and check for bilateral breath sounds with ventilation.
- 16. Remove the retractors and the cricoid hook when the tube is adequately positioned. Secure the tracheostomy tube around the neck with umbilical tape. Secure the flange to the patient's skin with four interrupted 2-0 nylon sutures.
- 17. Apply a sterile dressing around the tube.
- 18. A chest radiograph should be considered to assess tube placement above the carina and to ensure the absence of an iatrogenic pneumothorax.

To prevent infection, pneumomediastinum, or subcutaneous emphysema, do not close the skin incision around the tracheostomy tube. A tracheostomy tube provides access to the trachea for an unlimited amount of time. Once the indication for the tube has resolved, it is removed to allow the tracheocutaneous fistula to close spontaneously.

**Figure 199-11** Tracheal hook is placed in the cricoid cartilage and elevated anteriorly. The incision is made between the second and third rings.

#### **Complications**

- Bleeding
- Subcutaneous emphysema
- Wound infection
- Pneumomediastinum
- Pneumothorax
- Tracheoesophageal fistula
- Tracheoinnominate artery fistula
- Recurrent laryngeal nerve damage
- Aspiration
- Tube obstruction
- Malpositioned or displaced tube with subsequent hypoxia or death
- Tracheal stenosis
- Dysphagia
- Sepsis

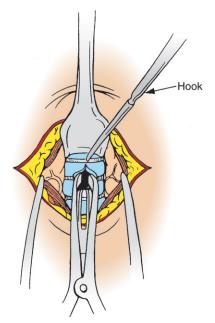

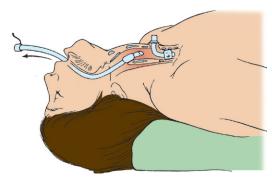

Figure 199-12 Insert the dilator into the trachea.

**Figure 199-13** Remove the endotracheal tube after inserting the tracheostomy tube.

**NOTE:** Placement of tracheostomies can be technically difficult, especially in children, obese patients, and patients with deformed or fixed cervical spines. Complication rates are higher in children. For these individuals, tracheostomies should definitely be avoided in emergency situations and performed under controlled circumstances.

#### **Postprocedure Patient Education**

Initially, the patient will be cared for in the hospital. Postprocedure education includes cleaning of the appliance and suctioning. If the patient is discharged with a tracheostomy, caretakers will need to continue this care at home. Patients will not be able to speak if the tube balloon is inflated. If the balloon is deflated, patients can eat normally and can speak if the tube lumen is occluded with the patient's finger during exhalation. A speaking valve can also be fitted to passively close the lumen during exhalation.

#### **CPT/BILLING CODES**

31600 Tracheostomy, planned (separate procedure)

31603 Tracheostomy, emergency procedure; transtracheal

31605 Tracheostomy, emergency procedure; cricothyroid membrane

31612 Tracheal puncture, percutaneous with transtracheal aspiration or injection

#### **ICD-9-CM DIAGNOSTIC CODES**

478.79 Unspecified diseases of larynx, not elsewhere classified (abscess, obstruction, necrosis)

518.5 Pulmonary insufficiency following trauma or surgery

518.81 Acute respiratory failure

518.83 Chronic respiratory failure

807.5 Fracture, larynx and trachea, closed

# PERCUTANEOUS ENDOSCOPIC GASTROSTOMY PLACEMENT AND REPLACEMENT

Paul W. Davis

Percutaneous endoscopic gastrostomy (PEG) is the placement of a percutaneous gastrostomy tube with the aid of an endoscope. The PEG technique has largely replaced surgical gastrostomy as the procedure of choice for patients who require long-term enteral nutrition. It was first described in 1980 by Gauderer and colleagues for use in children but has since gained wide acceptance for use in patients of all ages. Along with other necessary supplies, commercial PEG tube kits usually contain the PEG tube, an internal bolster (to seal the gastric mucosa), and an external bolster (to stabilize and prevent migration of the tube). Choices for the internal bolster including a balloon, a soft dome, crossbars, a T-bar, a flange, a disk, a three-leaf retainer, and others; most are soft to avoid irritating the gastric mucosa.

The actual PEG placement procedure requires two trained individuals, one of whom must be skilled in esophagogastroduodenoscopy (EGD). Please see Chapter 101, Esophagogastroduodenoscopy. for a full discussion of EGD; this chapter will be limited to the application of EGD for PEG placement. The procedure can be performed in the operating room, the endoscopy suite, or at the bedside. Normally, the procedure can be performed under moderate sedation (see Chapter 2, Procedural Sedation and Analgesia, and Chapter 7, Pediatric Sedation and Analgesia), with a local anesthetic such as lidocaine also used at the cutaneous site (see Chapter 4, Local Anesthesia). However, if intravenous sedative agents are unlikely to be effective because of a history of prescribed or illicit controlled substance use, or if the patient is at risk of respiratory compromise secondary to oropharyngeal anatomy, risk of aspiration, or a history of obstructive sleep apnea, a third skilled provider will be needed to provide sedation and monitor the airway. Indeed, endotracheal intubation may be advisable because these patients often have underlying conditions that impair handling of secretions. In these circumstances, the assistance of an anesthesiologist, nurse anesthetist, or trained primary care colleague is advantageous.

After PEG placement, there is no reason for routine removal; however, occasionally they require replacement owing to accidental dislodgement or because they have become obstructed, worn out, kinked, or fractured. Although most of these problems can be avoided with diligent care, this chapter also briefly discusses PEG replacement.

#### **INDICATIONS**

#### **Placement**

The decision for PEG placement has to be made on a case-by-case basis, especially when rapidly progressive and incurable diseases are

present. Certainly, this includes the various forms of severe dementia

Most commonly, PEG tube placement is performed for patients who are unable or unwilling to ingest food orally. The usual conditions include major head and neck trauma, esophageal cancer, oropharyngeal cancers, cerebrovascular accidents, esophageal dysmotility, as well as other irreversible neurologic conditions such as amyotrophic lateral sclerosis. When used for provision of nutrients, the choice of PEG placement necessarily requires a functioning gastrointestinal tract and optimally involves a prior discussion with the patient or family concerning prognosis and underlying comorbid conditions. Other uses for the PEG procedure include treatment of gastric volvulus, decompression of patients with an intestinal obstruction or peritoneal carcinomatosis, administration of unpalatable medications to pediatric and mentally impaired patients, and enhanced enteral feeding of patients with hypercatabolic states, such as burn patients.

In brief, PEG tubes have two primary indications:

- 1. Enteral access for feeding or medication administration
- 2. Decompression of the gut

#### Replacement

- Accidental PEG dislodgement or removal
- PEG blockage or obstruction
- PEG damage (e.g., worn out, kinked, fractured)

#### **CONTRAINDICATIONS**

#### **Placement**

#### **Absolute**

In general, any contraindication to endoscopy will apply to PEG insertion as well. In addition, the absence of one of three prerequisites for safe PEG placement is a good reason to abort the procedure. These prerequisites include ability to distend the stomach endoscopically with air, endoscopically visible finger invagination of the anterior gastric wall, and transillumination of the anterior abdominal incision site. Additional absolute contraindications include the following:

- Pharyngeal obstruction
- Esophageal obstruction
- Active coagulopathy
- Peritonitis
- Sepsis

- Recent myocardial infarction
- Hemodynamic instability

#### Relative

Either esophageal or oropharyngeal cancer is considered a relative contraindication because there is a theoretical potential for seeding of the gastrocutaneous tract with cancer cells. Although this hazard is rare, it is primarily seen with untreated oropharyngeal cancers, with an incidence of less than 1% in one reported series (Cruz and colleagues, 2005). Some have advocated use of the Russel or "poke" technique (see later), radiographically placed, or surgically placed gastrostomy tubes as more appropriate in this setting. With these techniques, the PEG tube is not drawn down the esophagus for placement.

The presence of gastroesophageal reflux with its attendant risk of aspiration has long been considered a contraindication to PEG. Historically, a surgically placed or, more recently, a radiologically placed jejunostomy tube has been preferred. However, jejunostomy does not prevent gastroesophageal reflux and it is now known that PEG placement may actually decrease reflux because the PEG effectively creates an anterior pseudogastropexy.

Other relative contraindications include the following:

- Portal hypertension
- Moderate or massive ascites
- Gastric varices
- Prior abdominal surgery
- Peritoneal dialysis
- Hepatomegaly or splenomegaly
- Large hiatal hernia
- Large ventral hernia
- Open abdominal wound
- Prior subtotal gastrectomy
- Morbid obesity
- Anorexia nervosa
- Infiltrative or malignant disorders of the stomach
- Limited life expectancy

#### Replacement

#### Absolute

- Immature PEG tract (e.g., <4 weeks after PEG placement)
- Existing PEG tube not removable with gentle, constant traction (endoscopic guidance necessary)

 Nonreplaceable catheter (e.g., needle jejunostomy with 5- to 7-Fr catheter)

#### Relative

- Jejunostomy (the tract can be stented with a replacement catheter, but more information should be obtained before resuming feedings)
- Witzel gastrostomy (these use a more circuitous tunnel and a smaller tube and may be difficult to maneuver)

#### **EQUIPMENT AND MATERIALS**

#### **Placement**

The equipment list in Chapter 101, Esophagogastroduodenoscopy, applies equally to the endoscopy needs of PEG placement. This includes topical benzocaine (e.g., Cetacaine, Hurricaine) spray, if desired. In addition, the following equipment and supplies are recommended (usually included in commercial PEG kits):

- Gloves and equipment necessary for clinician to follow universal blood and body fluid precautions
- Lidocaine 1% to 2% for local anesthesia of the skin and abdominal wall
- 22- and 25-gauge needles
- 50 or 10-mL syringe
- Antiseptic preparation solution such as povidone-iodine or chlorhexidine
- Scalpel with no. 11 blade
- 4 × 4 gauze sponges
- Fenestrated drape
- Introducer trocar
- Guidewire (standard or looped end, depending on technique used)
- Disposable snare for gastroscope
- Abdominal binder (for confused or impaired patients)
- PEG tube with external bolster
- Surgical jelly for PEG tube lubrication
- Large, 50- to 70-mL (e.g., Toomey) syringe to aspirate gastric contents
- Adapter to attach Foley catheter to feeding assembly or to cap it off
- Jejunal tube (if warranted)
- Low-profile device (Fig. 200-1)

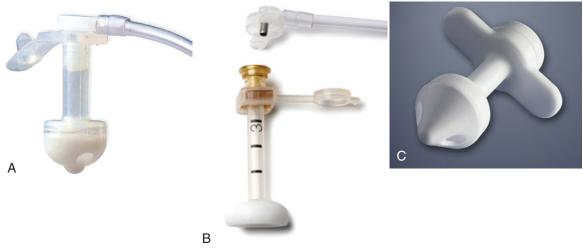

Figure 200-1 Low-profile devices (LPD). A, Bard Button. B, Bard Gauderer "Genie." C, Cook LPD.

#### Replacement

- Gloves and equipment necessary for clinician to follow universal blood and body fluid precautions
- Antiseptic preparation solution such as povidone-iodine or chlorhexidine
- 4 × 4 gauze sponges and adhesive tape
- Surgical jelly for PEG tube lubrication
- Foley catheter or commercial PEG replacement kit with PEG tube of similar diameter to the original PEG
- External bolster (Options include a retainer for a nasogastric tube, a short length [3 cm] of latex or Silicone tubing [cut from a Foley catheter or feeding tube] and a plastic cable tie or cut to form a T-bar, or a 0 or 2-0 silk suture. Commercial bolster kits are available; however, they are expensive, are not always available, and often do not properly fit the replacement PEG tube.)
- Large, 50- to 70-mL (e.g., Toomey) syringe to aspirate gastric contents
- Adapter to attach Foley catheter to feeding assembly or to cap it off
- Low-profile device (see Fig. 200-1)

#### PREPROCEDURE PATIENT PREPARATION

The patient or legal guardian or family member who will be caring for the patient and assisting with tube feedings should be given a general description of EGD and the PEG placement or replacement procedure. Any available alternatives should be discussed. The possible risks and complications of these procedures need to be explained along with the symptoms and signs that might suggest late complications and problems. It is very important that caregivers be included in this conversation because patients requiring PEG frequently suffer from cognitive or neurologic impairments. Informed consent forms should be signed before EGD and PEG placement. It is prudent to provide a patient education handout and instructions to follow before the procedure(s). Diagrams and photographs are particularly useful for helping patients and families understand the anatomy and altered feeding pathway proposed with PEG placement.

Before PEG replacement, there may be an opportunity to explore with the patient or family whether PEG feeding is still the desired method of nutritional support. There may also need to be a discussion about PEG care to avoid the need for future replacement. The patient should experience minimal discomfort with PEG replacement; if there is more than minimal discomfort, the PEG should not be manipulated. Small children or anxious patients may benefit from mild sedation.

For PEG placement, it is essential to know if the patient is taking any anticoagulants or platelet-inhibiting medications and to withhold these for an appropriate interval before the procedure to minimize any risk of bleeding. The patient must have all solids and liquids withheld for at least 8 hours before the procedure to minimize risk of esophageal reflux and aspiration. Solids may need to be withheld for longer if diabetic gastroparesis or a similar neuropathic condition is present. The presence of a large phytobezoar in the gastric lumen may impair visualization of the gastric indentation by the assistant's finger as well as the sounding needle. Unless EGD is necessary, these precautions are not needed for PEG replacement.

#### **Antibiotic Prophylaxis**

Although antibiotic prophylaxis is neither necessary nor recommended for endoscopic procedures according to the most recent American Heart Association guidelines (see Chapter 221, Antibiotic Prophylaxis), preprocedure antibiotic administration is recommended before PEG insertion because of the risk of infection of the gastrocutaneous tract from oropharyngeal and cutaneous flora. It is important to recognize that PEG placement is a "clean" procedure, not a sterile procedure, and every effort should be made to

make it as clean as possible. Usually, a cephalosporin or fluoroquinolone is satisfactory unless special considerations are present, such as methicillin-resistant <code>Staphylococcus</code> aureus (MRSA) or <code>Enterococcus</code> colonization of the skin or oropharyngeal cavity. Refer to recommendations later in the discussion of abscess and wound infection in the section on Postprocedure and Late Complications. If there is no sign of local irritation or infection and only minimal discomfort is experienced during the procedure, antibiotic prophylaxis is rarely necessary during PEG replacement.

#### **TECHNIQUE**

#### **Placement**

#### **Patient Positioning**

- The head of the patient's bed or gurney should be elevated 30 degrees to decrease the risk of aspiration of oral or gastric secretions.
- 2. The patient may be placed in either the left lateral decubitus or the supine position. Although the supine approach offers an added challenge for the endoscopist to identify the larynx and esophagus, this is more than compensated for by not having to rotate the patient after scope insertion.

#### **Anesthetic Administration**

At this point, conscious sedation can be achieved with appropriate intravenous medications. Depending on the endoscopist's preference, the posterior oropharynx and hypopharynx can be anesthetized with a topical anesthetic such as benzocaine spray.

#### **Endoscope Insertion and Evaluation**

- 4. Before introducing the gastroscope, it is essential to examine the oral cavity and oropharynx for food, debris, and retained secretions, which are quite common in patients undergoing this procedure. It is important to manually remove or suction this material to prevent aspiration during the procedure.
- 5. The gastroscope is then introduced and passed into the hypopharynx. Esophageal intubation can be difficult because of underlying pathology or the patient's inability to follow commands to swallow. One technique that can be helpful is to pass a snare catheter through the working channel of the scope and then into the proximal esophagus posterior to the arytenoid cartilages on either side of the visualized vocal cords. The gastroscope is then advanced over the closed snare catheter into the esophagus. The catheter is then retracted into the working channel before proceeding with the procedure.
- 6. It is prudent to perform a complete diagnostic examination of the esophagus, stomach, and duodenum before PEG placement. If a lesion is discovered that will require biopsy or some other therapy, this should be done after PEG placement.
- 7. Once the gastroscope is in the stomach, all residual fluid and food should be suctioned so that the stomach is completely empty. Occasionally, the standard-caliber endoscope cannot be passed beyond an esophageal stricture or tumor; use of a slim or ultrathin endoscope may be necessary. Rarely will esophageal dilation be required to advance the scope beyond an obstruction.

#### Identification of Percutaneous Endoscopic Gastrostomy Abdominal Insertion Site

8. Once the gastroscope is in the stomach, the second endoscopist (or trained assistant) can expose the anterior abdominal wall and carefully examine it for signs of transillumination. If necessary, the high light intensity feature on the light source can be used to help identify the insertion site. The assistant may also use a finger to palpate and indent the anterior abdominal wall; the endoscopist should then be able to visualize the

Figure 200-2 Endoscopic visualization of finger indentation.

corresponding indentation in the anterior wall of the stomach (Fig. 200-2).

**NOTE:** If a suitable site is not identifiable by either transillumination or finger palpation (preferably both), the procedure should be abandoned.

- 9. By convention, a PEG entry site is sought in the left upper quadrant of the abdomen, although a site to the right of midline is satisfactory as well. A site located a few centimeters below the costal margin will be more comfortable for the patient in the long run and will help prevent inadvertent laceration of the liver or spleen. Many endoscopists prefer a more distal site, in the anterior antrum. If the initial or subsequent plan is to convert the PEG to a jejunal enteral tube (PEG-J), an antral entry site will facilitate its advancement through the pylorus and beyond the ligament of Treitz, a measure found to minimize the risk of retrograde migration of the jejunostomy tube.
- 10. The assistant then prepares the anterior abdomen with an antiseptic solution, changes into sterile gloves, and covers the chosen site with a fenestrated sterile drape. Commercial PEG kits usually include a local anesthetic like lidocaine along with a syringe, a 22-gauge needle, and a 25-gauge needle. The anesthetic can be drawn up into the syringe using the 22-gauge needle and the smaller needle can be used to raise a skin wheal at the proposed entry site. The longer 22-gauge needle can then be reattached to the syringe.
- 11. As the assistant then passes the sounding needle through the abdominal wall into the stomach, the endoscopist watches for entry of the needle through the gastric wall. Some endoscopists recommend keeping slight negative pressure on the syringe plunger while the needle is advanced; if air enters the syringe before visualization of the needle in the gastric lumen, it can be presumed that the needle has entered another hollow viscus like the colon or a loop of small intestine. The needle is then withdrawn and another insertion site sought.

#### Percutaneous Endoscopic Gastrostomy Tube Placement

- 12. Once a suitable PEG insertion site has been identified, the assistant injects an additional 3 to 5 mL of anesthetic intradermally, and a no. 11 scalpel blade is used to make a horizontal or vertical skin incision.
- 13. While the assistant obtains the needle catheter from the PEG kit, the endoscopist can advance the snare catheter through the working channel of the gastroscope and into the gastric lumen.
- 14. The assistant then inserts the catheter rapidly through the skin incision and into the gastric lumen (Fig. 200-3), making certain that the catheter is directed at the same angle with

Figure 200-3 Introducer trocar visualized entering the gastric lumen.

respect to the skin as was just used with the sounding needle. This rapid "poke" should not be too slow or cautious; an assertive poke is necessary to ensure that the tip of the catheter successfully penetrates the tough gastric serosa instead of merely rebounding from the gastric wall.

15. As soon as the tip of the needle catheter enters the gastric lumen, the endoscopist snares it to hold it in place (Fig. 200-4). The assistant then withdraws the inner needle, leaving the outer plastic "introducer catheter" in place.

**A.** "PULL" TECHNIQUE. This is the most commonly used method of PEG placement, accounting for approximately 90% of PEGs.

- 16a. A looped guidewire is threaded through the catheter (Fig. 200-5) and this is grasped with the snare.
- 17a. The endoscope, along with snared guidewire, is withdrawn through the esophagus and out of the mouth under direct visualization.
- 18a. The looped guidewire is then released and looped to the wire guide for the gastrostomy tube included in the kit.
- 19a. The "skin" assistant pulls on the guidewire where it enters the abdominal wall to advance the gastrostomy tube through the esophagus and into the stomach.
- 20a. As the guidewire exits the abdominal incision, the tapered gastrostomy tip will follow. It should be advanced until the terminal bumper is snug against the anterior gastric wall.
- 21a. Finally, the assistant disconnects the looped guidewire from the gastrostomy tube assembly.

**B.** "PUSH" TECHNIQUE. Alternatively, the "push" (or Sacks-Vine) technique can be used.

**Figure 200-4** The snare is advanced through the working port of the gastroscope and here is seen looping around the introducer catheter.

**Figure 200-5** The guidewire is advanced through the introducer catheter and the catheter is subsequently removed.

- 16b. A standard (nonlooped) guidewire is threaded through the catheter (see Fig. 200-5) and grasped with the snare.
- 17b. The endoscope and snared guidewire assembly is withdrawn as a unit through the esophagus and out of the patient's mouth. Enough of the guidewire has to be threaded out of the mouth to enable the gastrostomy tube to be completely threaded over the guidewire (Fig. 200-6) so that it extends beyond the internal bolster on the proximal end.
- 18b. Both ends of the guidewire are then grasped in such a fashion as to create slight tension. The endoscopist maintains a firm grasp on this proximal end of the guidewire while the "skin" assistant maintains control of the abdominal end.
- 19b. The endoscopist then advances the gastrostomy tube over the taut guidewire, pushing the internal bolster into the patient's mouth until the dilating tip protrudes through the abdominal wall
- 20b. The assistant then pulls the gastrostomy tube through the abdominal wall until the internal bolster is snug against the anterior gastric wall.
- 21b. Finally, the guidewire is removed from the abdominal end.

#### Postprocedure Endoscopy

22. The endoscope is reinserted after the gastrostomy has been pulled or pushed into place. This allows careful examination of the esophagus, stomach, and visible surrounding structures for any mucosal or other trauma caused during the procedure as well as confirmation of proper placement of the internal bolster adjacent to the anterior gastric wall (Fig. 200-7). A photograph is taken and any necessary biopsies are performed at this time.

**Figure 200-6** Threading the "push" percutaneous endoscopic gastrostomy tube over the guidewire.

**Figure 200-7** Endoscopic photograph of proper placement of internal bolster.

#### Post-Percutaneous Endoscopic Gastrostomy Placement

- 23. Once appropriate positioning of the internal bolster is confirmed, the endoscope is removed and an external bolster is slipped into place with the aid of some lubricant applied to the protruding gastrostomy tube.
  - NOTE: Extra care must be taken when placing the external bolster to make sure it is not too tight. This will prevent such complications as PEG site infection, tissue necrosis, PEG entry site leakage, and "buried bumper syndrome" (see section on Postprocedure and Late Complications). Optimal external bumper placement allows the clinician's gloved index finger to slip easily between the abdominal entry site and the bumper.
- 24. If necessary, trim excess PEG tubing with scissors, leaving enough tubing to be looped around and taped to the skin of the abdomen, about 13 to 15 cm. This is also an ideal length to allow a jejunal tube to be inserted through the PEG and advanced beyond the ligament of Treitz, if necessary.
- 25. After a few minutes have passed, allowing the stomach to decompress from air introduced during the procedure, a feeding adapter is placed into the external end of the PEG tube.
- 26. The PEG site is then cleaned with soap and water and a split 4 × 4 gauze sponge placed around the PEG tube but *over* the external bolster. This dressing is not placed under the bolster because this will only cause more pressure on the healing wound. Dressings are changed daily and the wound is kept clean until complete healing has occurred. Dressings are changed as needed thereafter (Fig. 200-8).
- 27. Orders should be written to initiate tube feedings, medication administration, and tube irrigation 4 hours after placement.

**Figure 200-8** Final result with percutaneous endoscopic gastrostomy tube in place after tract has healed completely.

#### Special Considerations

Patients with unresected esophageal or oropharyngeal malignancies deserve special consideration; using either the "pull" or "push" technique raises the potential for seeding the abdominal wall with tumor cells. This is particularly true of oropharyngeal tumors. In many cases, long-term survival is not expected so the PEG can be placed in the usual fashion. If the PEG is to be placed for nutritional support before the planned tumor resection and there is a chance for long-term survival or cure, some endoscopists recommend the Russel or "introducer" method using a dilator with a peel-away sheath. This technique uses the Seldinger technique and fluoroscopy for placing an inflatable gastrostomy tube with a internal balloon bolster. The endoscope is used for direct visualization as well as to provide mucosal counterpressure during PEG insertion. The balloon tip is then inflated and an external bolster placed to secure the device. Advantages include the low risk of direct contamination of the tract with oral flora or malignant cells as well as a single passage of the gastroscope during the procedure and the avoidance of mucosal injury by the PEG tube during transesophageal passage (Vargo and Ponsky, 2000).

Obese patients present a special challenge. Transillumination of the abdominal wall may not be successful and the thickness of the subcutaneous layer may preclude successful sounding of the gastric lumen with the 1½-inch, 22-gauge needle. In this case, the PEG entry site can be identified by finger palpation alone, the skin and subcutaneous tissue anesthetized with lidocaine, and a transverse incision made with the scalpel down through the subcutaneous layer to the fascia. Transillumination should be possible at the base of the incision. Use of the high light intensity feature may be necessary and the stomach is then sounded with the 22-gauge needle, with additional local anesthetic provided for the patient's comfort.

Prior abdominal surgery is not an absolute contraindication to PEG placement but a PEG entry site should be found that is away from the surgical scar. Careful sounding can be performed using the technique described previously to identify an interposed air-filled viscus. If air enters the syringe before the sounding needle is seen in the gastric lumen by the endoscopist, the procedure should be aborted. Otherwise, a safe tract is confirmed by endoscopic visualization of the intragastric needle tip and concurrent aspiration of air from the syringe.

#### **TECHNIQUE**

#### Replacement

Perhaps more commonly than placing a PEG tube, primary care clinicians may be called on to replace one. This may be due to the PEG becoming dislodged (which is more common in confused or uncooperative patients) or nonfunctional (due to blockage or obstruction, fracture, or leaking). Techniques for attempting to clear blockage are discussed in a following section. Partial dislodgement presents a unique diagnostic challenge and can present as pain, buried bumper syndrome, or PEG tube blockage. Diagnostic approaches are also described for those complications in the section on Postprocedure and Late Complications. The management approach depends on the timing of dislodgement because the gastrocutaneous tract takes about 4 weeks to heal and mature. Therefore, as much information as possible should be gathered about the existing or prior PEG tube, especially regarding the procedure used to place the PEG, how long ago it was placed, and the type of PEG and internal bolster.

## Dislodged Percutaneous Endoscopic Gastrostomy, Closed Mature Tract (≥4 Weeks after Placement)

Depending on the age, maturation, and diameter of the PEG, tracts begin to close as soon as the tube is removed; therefore, every effort should be made to replace a dislodged PEG tube as soon as possible. A lost tract may require a repeat procedure. Dilation of a closing

PEG tract has been described using filiform catheters and followers adapted from urology (see Chapter 110, Bladder Catheterization [and Urethral Dilation]); however, consultation with a gastroenterologist or surgeon may be beneficial.

### Dislodged Percutaneous Endoscopic Gastrostomy, Open Mature Tract (≥4 Weeks after Placement)

- 1. If the original PEG tube is in good condition, after the balloon is deflated it can simply be reinserted. Alternatively, a Foley catheter of similar diameter can be used. Either tube will act as a stent until a permanent replacement can be found.
- 2. Lubrication should be applied liberally to the tube being used for replacement, and it should then be gently inserted through the existing tract. This can be done without endoscopy.
  - **NOTE:** Do not advance the tube against significant resistance; advancement against anything more than mild resistance can result in complications. Replacement should be painless and not require dissection or force. If these conditions occur, the procedure should be aborted.
- 3. Make sure that the balloon is well within the gastric lumen, and then slowly and carefully reinflate it with saline. Gentle external traction on the PEG tube should then be used to draw the balloon snugly against the anterior gastric wall. Plans for a permanent replacement PEG tube can then be made.
  - **NOTE:** Inflation of the balloon within the gastrocutaneous tract can result in pain, hemorrhage, disruption of the tract, and even peritonitis.
- 4. Unless changes are deemed necessary, a permanent replacement PEG tube, often found in a commercial kit, should be similar in diameter and function to the original. Placement of a low-profile PEG tube (see Fig. 200-1) may prevent recurrence of dislodgement. Alternatively, a standard PEG tube can be used and an abdominal binder placed to prevent the patient from pulling the tube out again.
- 5. After any replacement, aspirate gastric contents with a large syringe or use gravity drainage of gastric contents to confirm placement. After the balloon is reinflated, pull the catheter snug to lodge the internal bolster against the anterior gastric wall, immediately behind the anterior abdominal wall. If there was any difficulty with replacement of the PEG tube, or if the return of gastric contents is equivocal, a water-soluble contrast study should be obtained before resuming feedings. This will also ensure proper positioning of the internal bolster. A small amount of water-soluble, radiopaque contrast material is injected through the PEG tube, and a flat plate radiograph of the abdomen obtained. It should show intraluminal distribution of the contrast material.

**NOTE:** If the patient is known to have a jejunostomy tube, after stenting the tract with a replacement catheter, more information should be obtained before resuming feeding.

6. Perhaps more important than for the original PEG tube, unless a low-profile version is used (see Fig. 200-1), special attention should be paid to securing the external bolster for a replacement PEG. After bolstering, the catheter should be at approximately 90 degrees to the skin and anterior abdominal wall. It should be fixated to prevent internal migration of the catheter. Initially, 4 × 4 gauze sponges can be stacked several inches to create a pyramid-shaped dressing and taped to the skin and PEG catheter. Another temporary option is to use the same equipment provided to secure a nasogastric tube. However, temporary bolsters should usually be converted to a more permanent bolster. One option is to wrap a short (3-cm) segment of latex tubing (cut from another Foley catheter or nasogastric tube) around the base of the PEG tube and secure it with a plastic cable tie. This short segment should be wrapped perpendicularly around the PEG tube at the

skin level, and the resultant friction between the tubes should prevent PEG slippage or migration. Alternatively, a T-bar can be made from such a short segment by folding it in half and cutting small nicks from the two folded corners. After unfolding the segment, the tip of a hemostat can be inserted through the resulting two diamond-shaped holes, and across the short segment. The hemostat can then be used to grasp the distal end of the PEG tube and draw it through the T-bar. Make sure the diamond-shaped holes are large enough to avoid compressing the PEG tube lumen. The T-bar can then be drawn to the appropriate location on the PEG tube, approximately 0.5 to 1 cm from the skin surface, to act as a bolster. Placing a suture in a manner similar to that used to secure a chest tube may also be effective. Take a large bite of skin adjacent to the PEG exit site; tie a loose square knot at skin level, and then wrap the loose ends of the remaining suture several times in opposite directions around the PEG tube, finally securing the suture to the PEG tube in a snug fashion with another knot. The resultant tube fixation should be firm but allow some slack to prevent pressure necrosis if the patient changes position.

After placement is confirmed and the PEG tube is bolstered, the end of the tube should be clamped, capped, or fitted with the appropriate feeding adapter.

#### Dislodged Percutaneous Endoscopic Gastrostomy, Immature Tract (<4 Weeks after Placement)

Management of early dislodgement (<4 weeks) is different. The stomach may have separated from the anterior abdominal wall, resulting in free perforation with spillage of gastric contents, peritonitis, fever, or sepsis. In this event, broad-spectrum antibiotics should be administered, a nasogastric tube placed, and surgical consultation obtained. If the stomach has not separated from the anterior abdominal wall, a PEG tube can be replaced endoscopically, either through the same site or through a new one. Alternatively, the tract may be allowed to close spontaneously and a replacement PEG placed in 7 to 10 days if the patient remains stable.

#### Nonfunctioning Percutaneous Endoscopic Gastrostomy Needing Replacement

Again, as much information as possible should be gathered about the existing PEG tube, especially regarding the procedure used to place the PEG, how long ago it was placed, and the type of PEG and internal bolster.

1. If the PEG has a balloon for an internal bolster, deflation of the balloon should allow removal and replacement. If the balloon will not deflate, which is not unusual in long-standing PEG tubes, the inflation port may be clogged or damaged. Careful insertion of a guidewire into the balloon port may unclog it. If this attempt is unsuccessful, slightly further insertion of the guidewire may rupture the balloon. Alternatively, the balloon can be drawn close to the anterior abdominal wall by putting tension on the PEG tube. A needle inserted through the PEG tube can then be used to rupture the balloon. If these fail, endoscopic rupture of the balloon may be necessary. Another option is to cut the PEG tube close to the ports, which may allow the balloon to deflate on its own. After cutting, a firm external grip must be maintained with a clamp or hemostat on the portion of PEG tube remaining within the patient to prevent migration down the gastrointestinal tract; such migration may require endoscopic or surgical retrieval. If the PEG tube gets away and migrates, the majority of tubes will pass the gastrointestinal tract without incident and they can often be followed with plain radiographs every 48 hours, but there are reported cases of bowel obstruction and perforation. Endoscopic or surgical retrieval may be necessary for hardware that does not pass within 2 to 3 weeks or if the patient experiences obstructive symptoms. The risk of obstruction increases in children younger than 6 years of age or weighing less than 40 kg.

If the type of internal bolster cannot be determined or if it is thought to be soft or pliable, the application of constant, gentle external traction often results in PEG removal. Most PEGs can be removed in this manner.

**NOTE:** Never apply more than gentle traction when attempting to remove a PEG tube; either the internal bolster has become imbedded in the gastric wall or it was not intended to be removed externally and will likely need to be removed endoscopically.

#### **COMPLICATIONS**

Although deaths are not often directly attributable to the procedure, perioperative and postprocedure survival after PEG placement is exceedingly poor. In one study of 714 patients, 5.6% of patients died within 7 days of the procedure, whereas 22%, 31%, and 48% were dead at 30 days, 60 days, and 1 year from the procedure, respectively. The primary hospitalization mortality rate was 11%, with 50% of these patients dying within 1 week of PEG placement. Preprocedure predictors of mortality include older age, hemodialysis, mechanical ventilation, cancer, and coronary artery disease. Median survival for patients older than 70 years of age was less than 6 months, with length of survival decreasing rapidly with older age (Smith and colleagues, 2008).

It is important to emphasize to patients and caregivers that studies suggest PEG placement does not significantly alter survival. On retrospective review, many patients could have been fed or hydrated through a nasogastric tube until recovery or death. Thus, when obtaining informed consent, it is essential that the clinician emphasize both the direct technical risks of the PEG as well as the anticipated natural course of the patient's underlying medical condition(s). This being said, complications can be discussed in three categories: (1) complications of upper endoscopy, (2) direct complications of PEG placement, and (3) postprocedure complications.

#### Complications Associated with Endoscopy

The most common complications associated with endoscopy include aspiration, hypoxemia, hypotension, acute myocardial infarction, hemorrhage, and esophageal perforation. The cardiopulmonary complications are actually primarily related to conscious sedation. Refer to the respective chapters for a full discussion, including prevention, identification, and treatment. Reported mortality rates for upper endoscopy are exceedingly low, on the order of 0.005% to 0.01%, but these studies primarily include healthy patients, not the severely debilitated and poorly nourished patients requiring PEG feeding tubes. However, because the complications are serious, a careful and complete discussion with the patient or legal guardian before the procedure is essential.

#### Direct Complications of Percutaneous Endoscopic Gastrostomy Placement and Replacement (to a Lesser Degree)

- Pneumoperitoneum: This finding is very common (35% to 50% incidence) and usually follows a benign course. It results from air escaping from the stomach during the course of a prolonged EGD during PEG placement, possibly compounded by multiple abdominal needle punctures and excessive air insufflation. Conservative management is usually acceptable. If the patient develops signs of increasing intra-abdominal air, sepsis, peritonitis, a systemic inflammatory response, or air in the portal or mesenteric veins, surgical consultation will be necessary (Vargo and Ponsky, 2000).
- Abdominal wall bleeding: This is usually identified soon after PEG
  placement and is caused by nicking or puncturing an abdominal
  wall blood vessel. Risk can be minimized by avoiding a tract near
  the midline through the rectus abdominis muscle. Hemostasis can
  often be obtained by tightening the external bolster against the
  abdominal wall to provide compression. Care must be taken to

loosen the bolster again within 48 hours to prevent skin and mucosal maceration and ulceration. If bleeding is significant, standard resuscitative measures should be used. A standard "crash cart" should always be immediately available whenever an endoscopic procedure is performed.

- Intraperitoneal and retroperitoneal bleeding: Symptoms and signs that this has occurred include hypotension, decreasing hemoglobin or hematocrit, abdominal pain, a rigid abdomen, and an absence of blood seen endoscopically. It can occur from laceration of the liver, spleen, or a deep blood vessel. Diagnosis is confirmed by computed tomography (CT) imaging and treatment is by immediate surgery. Surgical consultation with possible evacuation of the hemoperitoneum, repair of any solid organ injury, control of bleeding, and revision of the gastrostomy is indicated.
- Colon injury: Prior abdominal surgery or anatomic variation may result in the transverse colon being displaced over the anterior gastric wall. Careful attention to the special instructions provided previously will minimize this complication. The usual presentation is peritonitis and the appropriate intervention is usually intravenous antibiotics and surgery. Occasionally, nonoperative management can be considered if the patient is hemodynamically stable and there are no signs of sepsis.
- Hepatic injury: This complication has been described only rarely and can be prevented by careful attention to the precautionary steps during placement. Close observation is often all that is necessary unless there is associated hemorrhage.
- Splenic injury: Splenic perforation or rupture has never been reported with PEG placement but has occurred rarely with other upper endoscopic procedures. It should be suspected if the patient develops hypotension or abdominal pain and resuscitation should immediately be initiated intravenously with crystalloid solution until blood is available. If the patient is hemodynamically stable, confirmation can be made by CT. Immediate surgical consultation with laparotomy and splenectomy is necessary if the patient becomes unstable.
- Small bowel injury: Small bowel perforation is often occult and difficult to diagnose early. Fortunately, this complication is rare because the small intestine is protected by the greater omentum, which prevents it from migrating into the upper abdomen. However, if the patient has postoperative adhesions or the omentum has been previously resected, this injury can occur. It becomes clinically significant if there is intra-abdominal leakage and consequent peritonitis or if an enterocutaneous fistula develops. Fistulas often come to light only after the PEG is manipulated or replaced.
- Gastro-colo-cutaneous fistula: This is a rare complication of PEG placement and occurs when the PEG is inserted directly through the lumen of the large bowel into the stomach, usually near the splenic flexure. The patient may have transient ileus or fever but often remains asymptomatic for months, the diagnosis being made only after gastrostomy tube replacement. In most cases, there is no evidence of stool leakage or fistula formation. If the replacement tube is inserted into the colon rather than the stomach, diarrhea becomes evident when feedings are restarted. This complication is prevented by careful attention to the details outlined in the Technique section. Good transillumination and finger palpation are paramount to avoidance. The diagnosis is made radiographically by introducing contrast through the PEG tube. Most can be managed nonsurgically by removing the PEG and allowing the fistula to close spontaneously. A surgeon can be consulted if an abscess forms or peritonitis develops.

# Postprocedure and Late Complications Related to Percutaneous Endoscopic Gastrostomy Placement and Replacement

 Pain at the PEG site: This complication is also the primary presenting symptom of many of the complications listed in the fol-

- lowing. Careful attention to proper technique during PEG placement and proper cleanliness and care after placement are essential to preventing pain and discomfort. An attentive and prudent diagnostic approach to uncover the cause of pain will usually be rewarded.
- PEG tube blockage or obstruction: This problem is extremely common, occurring in up to 45% of patients. Prevention is the key, with liberal PEG tube flushing using 30 to 60 mL of water every 4 hours with a large syringe. This should also be performed after feeding and medication administration, as well as after checking residual volumes. Saline solutions should be avoided because the salt tends to crystallize in the channel and gradually form a blockage. Liquid formulations of medication are preferred and bulking agents such as psyllium seed and resins like cholestyramine should be avoided. A variety of treatments are effective in unclogging PEG tubes. Plain warm water has been shown to be the best irrigant, with carbonated beverages also proving effective. Pancreatic enzymes mixed with bicarbonate have been effective for dissolving more resistant proteinaceous blockages, the solution being allowed to sit in the tube for several hours before flushing copiously with warm water. If these methods prove ineffective, commercially available plastic brushes can be used to manually clear the tube. Wires and metal brushes should be avoided because of risk of perforation. Endoscopic snares, biopsy forceps, or Fogarty catheters have been used successfully; however, consultation with a gastroenterologist or surgeon may be helpful. Before any of these maneuvers, make sure the tube is not kinked at the bolster; merely unkinking it may correct the blockage.

**NOTE:** Do not force irrigation fluid into the PEG tube because it may rupture and injure the patient.

- Abscess and wound infection: Peristomal wound infection is common in patients not receiving perioperative antibiotics. The incidence is 18% and can be reduced to about 3% with appropriate antibiotic prophylaxis. MRSA has emerged as a significant pathogen, and at least one study has shown that nasopharyngeal decontamination before planned PEG insertion can result in a significant reduction in the incidence of wound infections (Horiuchi and colleagues, 2006). If the patient has been hospitalized or institutionalized for a prolonged period or if there is any suspicion of colonization, a nasopharyngeal culture and sensitivity should be performed. A 10-day course of an appropriate antibiotic (trimethoprim/sulfamethoxazole, clindamycin, or vancomycin) is recommended before PEG placement. A confirmatory test to ensure MRSA eradication should be performed before the procedure.
- Peristomal leakage: This is a very common and significant problem that is often seen in patients with diabetes, immunodeficiency, and malnutrition. Other factors that have been implicated include wound infection, peristomal abscess, hypersecretory syndromes, traction on the PEG tube, and buried bumper syndrome. Treatment is aimed at correcting these underlying conditions as well as using barrier creams such as zinc oxide. If hypersecretion is thought to be a contributing factor, agents like hyoscyamine or glycopyrrolate can be administered. Replacing the PEG tube with a tube of larger diameter should be avoided because this frequently only exacerbates the problem. If all else fails, the PEG tube can be removed for a few days, any infection treated, and the tract allowed to heal, scar, and partially close before a new tube is placed. Alternatively, the PEG tube can be removed completely and a new PEG site chosen.
- Diarrhea: Diarrhea is common among patients receiving enteral feeding, occurring in 10% to 20% of patients. The possible causes are manifold, including infection, protein malnutrition, medications, and administration of hyperosmolar enteral solutions. Patients can also have other dietary contributors, including lactose intolerance, fat malabsorption, or celiac disease. Common pharmaceutical culprits include magnesium-containing antacids,

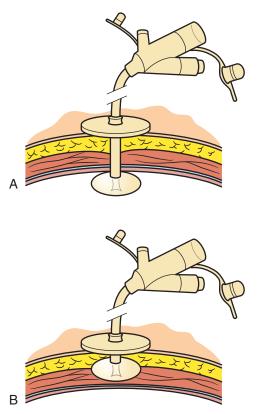

proton pump inhibitors (PPIs), antibiotics, prokinetic agents like metoclopramide, and hyperosmolar drug solutions. Management involves identifying the etiology and treating the patient accordingly. Protein malnutrition may require nutritional supplementation and delivery of isotonic feedings in the interim. Discontinuing unnecessary medications, using intravenous alternatives, and changing to a different brand or class of medication are all useful strategies. Antidiarrheals like loperamide are useful for some patients with medication-associated diarrhea. It is important to rule out pseudomembranous colitis and the rare cases of enterocutaneous fistula if diarrhea persists in spite of standard diagnostic and therapeutic measures.

- Gastrointestinal bleeding and ulceration: Gastrointestinal bleeding is a relatively infrequent late complication and occurs in about 2% of patients. It is caused by esophagitis, peptic ulcer disease, gastric pressure ulcers, and, rarely, erosion of the PEG tube into a gastric wall blood vessel. Once endoscopic diagnosis is determined, bleeding caused by a punctured gastroepiploic vessel in the stomach wall can be treated by tightening the external bolster against the abdominal wall, thus internally compressing the bleeding vessel. Care should be taken to loosen the bumper again within 48 hours to prevent pressure necrosis. Esophagitis and peptic ulcers can both be prevented and treated with PPIs; histamine type 2 receptor antagonists have not been noted to be very effective, especially in the former case. Gastric pressure ulcers are caused by the PEG tube and can occur either anteriorly, from direct pressure of the internal bolster, or posteriorly, caused by tall internal bolsters or protruding tips from Foley-type PEG tubes. Treatment is removal of the offending tube and replacement, which can often be done nearby (Fig. 200-9). Use of a low-profile device or a balloon-tipped device with a short (<3 mm) protruding tip for the replacement may minimize risk of recurrence. Use of a PPI alone will often be insufficient to heal
- Ileus and gastroparesis: Occasionally, postprocedure gastroparesis develops and can take longer than the usual 3 to 4 hours to resolve. Metoclopramide, erythromycin, or domperidone can be administered with good results in most cases. However, if persistent vomiting or abdominal distention occurs, the PEG should be unclamped to allow decompression and feedings should be discontinued for 24 to 48 hours. If abdominal distention and pain persist, an ileus should be suspected and perforation and peritonitis need to be ruled out. Often the cause is merely excessive pneumoperitoneum from the PEG procedure. Treatment often consists of nasogastric tube decompression, discontinuance of contributing medications, and clinical support. Intravenous broad-spectrum antibiotics and surgical consultation may be required if perforation is suspected.
- Aspiration: The risk of aspiration during the PEG procedure has already been discussed. The risk of aspiration, however, is much greater as a late complication and increases with supine positioning, use of sedative agents, advanced age, and neurologic impairment. Unfortunately, these are precisely the risk factors that

**Figure 200-9** Healing pressure ulcer at previous percutaneous endoscopic gastrostomy (PEG) site with PEG tube placed at new site.

- predispose patients to need PEG placement. Again, prevention is superior to treating the sequelae of aspiration. The primary clinician is advised to avoid excessive use of sedative agents and the patient/caretaker is instructed to keep the head of the bed elevated for several hours after feedings.
- Gastric outlet obstruction: The presenting complaint is usually intermittent vomiting or upper abdominal cramping and the cause is generally distal migration of the PEG tube. It is much more common with Foley-type gastrostomy tubes with the balloon lodging in the pyloric channel or duodenum, creating an intermittent obstruction. In children, a displaced internal bolster can get wedged in the gastric outlet. Prevention is the best approach by ensuring proper placement of the external bolster. Diagnosis can be made by an upper gastrointestinal series or endoscopically. With the Foley-type tube, the balloon can be deflated and the tube repositioned and reinflated with proper external bolster positioning.
- Buried bumper syndrome: This is a rare (1% to 2%) but potentially serious complication that occurs late after PEG insertion, after an average of 4 months, but reported from 2 months to 7 years after PEG placement (Schrag and colleagues, 2007). The internal bumper retracts into the anterior gastric wall (Fig. 200-10) and becomes lodged at some point along the gastrocutaneous tract, resulting in either a partial or complete PEG obstruction. The gastric mucosa can completely reepithelialize the internal stoma, resulting in an inability to infuse feedings or medication. This is the usual presenting complaint, along with abdominal pain at the PEG site. Diagnosis can be made radiologically, endoscopically, by ultrasonography, or by endoscopic ultrasonography. The buried bumper should be removed regardless of whether the patient is symptomatic. Removal can be achieved surgically, endoscopically, or through a combination of approaches. Use of a needle knife through the biopsy port of the endoscope has been

**Figure 200-10** Buried bumper syndrome. **A,** Proper percutaneous endoscopic gastrostomy tube placement. **B,** Buried bumper with regrowth of gastric mucosa over gastrocutaneous tract.

found to be effective. A mucosal incision is made over the buried bumper to allow its mobilization and removal. A fresh PEG tube can then be inserted under endoscopic guidance. Occasionally, a more extensive surgical procedure is required.

- Necrotizing fasciitis: As noted earlier, pressure from the PEG tube and external bumper on the peristomal site can lead to this lethal complication. Patients who are diabetic, malnourished, or otherwise immunocompromised are predisposed and at increased risk, as are those with wound infections. Prevention is by proper placement and adequate spacing of the external bolster. There is good evidence that multiple aerobic and anaerobic organisms are synergistically responsible for necrotizing fasciitis. Treatment involves wide surgical débridement, broad-spectrum antibiotics, and planned operative reevaluation. Patients require transfer to the intensive care unit with extensive multisystem support.
- PEG site herniation: This complication has been reported only once in the literature and was a late sequela of deep ulceration. The diagnosis should be suspected whenever there is a peristomal bulge noted with Valsalva maneuver. It is confirmed by CT and repair, if indicated, is surgical.
- Volvulus around PEG tube: This rare complication is seen primarily in the pediatric population and can involve the small intestine, transverse colon, or stomach. It is more common if the PEG is introduced through the posterior wall of the stomach, which can lead to rotation of the gut and consequent volvulus. Prevention is by careful attention to placing the PEG through the anterior wall of the stomach with proper external bolster placement in order to achieve close apposition of the anterior gastric wall to the parietal peritoneum. Treatment requires surgical consultation with exploratory laparotomy, reduction of the volvulus, and repositioning of the gastrostomy. Gastropexy to the anterior abdominal wall may decrease the incidence of recurrence.
- Tumor implantation in PEG tract: As already mentioned, this late complication is extremely rare, occurring primarily in patients with oropharyngeal tumors and in less than 1% of this group. Direct seeding during the PEG placement is the accepted primary mechanism, although hematogenous or lymphatic spread is also thought to occur. This complication offers an exceedingly poor prognosis, with a 0% 1-year survival. Placement of the PEG after primary tumor resection or by using the Russell technique (non-endoscopic, using a peel-away catheter) is a reasonable approach to lowering the risk of seeding (Cruz and colleagues, 2005).
- PEG tubes and pregnancy: PEG tubes can be used successfully during pregnancy, although persistent emesis has been reported. Conversion of the PEG to a PEG-J may be attempted and has been reported to be successful in this condition (Wejda and colleagues, 2003).

#### **POSTPROCEDURE CARE**

The external visible portion of the PEG tube can be cleaned with soap and water using a clean 4 × 4 sponge. Antibacterial ointment is not required and could result in inflammation caused by an allergy to one of the ingredients. A split 4 × 4 tracheostomy sponge is then placed over the external bolster—not between the bolster and the skin, which will cause excessive compression of the skin of the abdominal wall and possibly result in ostomy breakdown or buried bumper syndrome. The PEG tube is then looped back over the bolster and taped to the skin. If the patient is confused or unreliable, an abdominal binder can be placed to prevent manipulation and inadvertent removal of the tube. After 6 to 8 weeks, when the gastrocutaneous tract has healed and matured, the PEG can be removed and replaced with a low-profile device (see Fig. 200-1). This device is level with the skin with no permanent tubing extending from the abdominal wall, thus minimizing the opportunity for the patient to dislodge it.

Dressings over the PEG site are changed daily until there is no longer any drainage. The tube and ostomy site can be cleansed daily

or as needed with soap and warm water, taking care to débride excessive granulation tissue and dried secretions. Tube feeding, medication administration, and water flushes can be initiated 4 hours after placement. An example of postprocedure orders is provided online at www.expertconsult.com.

#### **PATIENT EDUCATION GUIDES**

The following materials are available online at www.expertconsult.com:

- Sample post-PEG procedure instructions
- Sample patient consent form
- Also see the patient education handouts for Chapter 2, Sedation and Analgesia, and Chapter 101, Esophagogastroduodenoscopy.

## ABDOMINAL PARACENTESIS

Eric Skye

Paracentesis, or an "abdominal tap," is an important clinical procedure for primary care clinicians. With the advent of new radiologic and minimally invasive techniques, diagnosis of intra-abdominal pathology has generally become less invasive. Nevertheless, paracentesis is the diagnostic test of choice in patients who have newonset ascites, in patients with suspected malignant ascites, and to rule out infection in those with preexisting ascites. In addition, therapeutic large-volume paracentesis (>4 L) remains an important treatment option for many patients, particularly those with diuretic-resistant ascites. If ultrasonography is available for guidance, it simplifies this procedure and decreases the risk of complications (see Chapter 225, Emergency Department, Hospitalist, and Office Ultrasonography [Clinical Ultrasonography]).

#### **ANATOMY**

Abdominal anatomy must be considered when performing paracentesis. Large volumes of ascitic fluid tend to float the air-filled bowel anteriorly and toward the midline when the patient is in the supine position. Other pelvic organs that must be considered include an overly distended bladder and a gravid uterus. In addition, the cecum is relatively fixed and less mobile than the sigmoid colon; thus, bowel perforation is more likely to occur in the right lower quadrant than in the left. Traditionally, the procedure has been performed through the linea alba using a midline insertion 2 cm below the umbilicus with the patient in a semiupright position (Fig. 201-1). Increasingly, a lateral approach has been advocated, with access 3 to 5 cm medial and cranial to the anterior superior iliac spine (Fig. 201-2). Using this approach, one must remain lateral to the rectus sheath to avoid the inferior epigastric artery. Paracentesis can be performed with the patient in the supine position or in the lateral decubitus position (or slight variants of these), which helps "float" the bowel away from the insertion site and can provide access to a deeper ascitic pool.

## **INDICATIONS**

#### Diagnostic

- New-onset ascites
- Suspected malignant ascites
- Rule out infection (consider for all hospitalized patients with known ascites)

## **Therapeutic**

- Temporary relief of tense ascites (causing gastrointestinal or cardiorespiratory symptoms such as pain or dyspnea)
- Symptom relief in patients with diuretic-resistant ascites

#### **CONTRAINDICATIONS**

#### **Absolute**

- Acute abdomen requiring immediate surgery (and even in this situation, paracentesis may be performed by the surgeon at the time of surgery)
- Coagulopathy when there is evidence of disseminated intravascular coagulation (DIC) or fibrinolysis

#### **Relative**

- Current bowel obstruction or severe bowel distention (consider ultrasonographic guidance; see Chapter 225, Emergency Department, Hospitalist, and Office Ultrasonography [Clinical Ultrasonography])
- Previous abdominal surgery (bowel may be adherent to abdominal wall, so perform in an area away from prior incision or, even better, consider ultrasonographic guidance because pockets of fluid may have formed)
- Anticoagulated patient or patient with coagulopathy without evidence of DIC or fibrinolyis should have the process reversed before paracentesis (see Precautions section).
- Pregnancy (ultrasonography-guided paracentesis is recommended after the first trimester)
- Distended bladder that cannot be emptied with a urinary catheter (consider ultrasonographic guidance)
- Obvious infection at the intended site of needle insertion (cellulitis or abscess)

## **EQUIPMENT AND SUPPLIES**

Commercially prepared kit or the following equipment:

- Skin cleansing solution (povidone-iodine or chlorhexidine)
- Sterile gloves and equipment necessary to follow universal blood and body fluid precautions
- Sterile marking pen (if area has not been marked indelibly before skin preparation)
- Sterile drapes
- 4 × 4 gauze squares
- 1% or 2% lidocaine with or without epinephrine
- 5-mL syringe for anesthetic
- 20-mL syringe for diagnostic paracentesis (also purple-topped blood collection tube for cell count, red-topped tubes for chemistries, blood culture bottles if infection suspected)
- 25- or 27-gauge, 1½-inch needle for local anesthesia
- 18-gauge,  $1\frac{1}{2}$  to 3-inch needle
  - Alternative devices: 18- or 20-gauge spinal needle, 18- or 20-gauge, 1½- to 3-inch angiocatheter needle, 3½-inch Caldwell needle (needle/cannula system designed for therapeutic large-volume

Figure 201-1 View of the midline approach with anatomic landmarks.

paracentesis; studies have suggested this is the most expedient technique), or catheter-over-wire system (Seldinger technique)

- No. 11 blade scalpel if large catheter to be inserted
- Sterile intravenous (IV) tubing
- 1-L vacuum bottles, a sufficient number if large-volume paracentesis is needed
- Foley catheter (if bladder decompression needed)
- Nasogastric tube (if gastric decompression needed)
- Three-way stopcock (for use with 50-mL syringe) (optional)
- 50-mL syringe, if using stopcock technique (optional)

## **PRECAUTIONS**

Careful attention to site selection as discussed in the section on Anatomy will minimize the risk of bleeding and injury to the bowel. In addition, entry near prior surgical scars should be avoided because there is a risk of adherent bowel loops near surgical scars. The *slow* introduction of the needle through the abdominal wall minimizes the risk of bowel injury because the needle can push mobile bowel away rather than injuring it. The application of intermittent

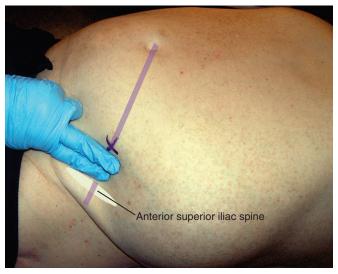

Figure 201-2 View of the lateral approach with anatomic landmarks.

negative pressure (aspiration) with the syringe while introducing the needle is generally preferred to constant negative pressure because the latter can quickly attract bowel or omentum on entry to the peritoneal cavity and occlude the needle. Needle occlusion can mask your entry into the peritoneal cavity and increase the risk of bowel injury as well as lead to a false sense of a "dry tap." Patients taking warfarin or who have any coagulopathy other than DIC or fibrinolysis should have the process reversed before paracentesis. If possible, antiplatelet medications should be held for 5 to 7 days. Warfarin can be held for 5 to 7 days (until the international normalized ratio [INR] normalizes) and the patient converted to lowmolecular-weight heparin during this time, with the dose being held the day of the procedure. Alternatively, the INR can be reversed the day of the procedure with fresh-frozen plasma. Some experts suggest that patients with thrombocytopenia or an abnormal INR (for reasons other than taking warfarin) can be given platelets or the INR reversed with factor replacement; however, this process is considered controversial and there are no data to support it.

#### PREPROCEDURE PATIENT EDUCATION

Explain the procedure to the patient outlining the indications relevant to his or her medical situation and the anticipated benefits (diagnosis, ruling out infection, or decreased symptoms from therapeutic paracentesis). Risks of the procedure, as noted in the Complications section, should also be explained and informed consent obtained. Discuss anticipated patient positioning and ensure the patient is able to maintain the desired position. The patient should be aware that the local anesthetic may cause some discomfort, as well as the needle (or catheter) used to perform paracentesis.

#### **TECHNIQUE**

- 1. Examine the abdomen, delineate areas of shifting dullness, and find landmarks. Mark if necessary. If clinical uncertainty exists about the presence of ascites, then ultrasonographic examination is recommended (see Chapter 225, Emergency Department, Hospitalist, and Office Ultrasonography [Clinical Ultrasonography]).
- Assess for bowel and bladder distention and use a Foley catheter or nasogastric tube, if necessary, to decompress the bladder or stomach (see Chapter 110, Bladder Catheterization [and Urethral Dilation], and Chapter 203, Nasogastric and Nasoenteric Tube Insertion). Consider ultrasonographic guidance if needed.
- 3. Position the patient in the semiupright or lateral position, as tolerated, if the infraumbilical approach is used (see Fig. 201-1). Place the patient in the supine position if the lateral approach is taken (patient may be tilted slightly to the side of collection for improved fluid collection; see Fig. 201-2).
- 4. Prepare the abdominal skin at the puncture site with povidone—iodine or chlorhexidine solution.
- Apply sterile drapes while confirming anatomic landmarks. The clinician should observe universal blood and body fluid precautions.
  - Midline approach: Insert the needle in the midline 2 to 3 cm below the umbilicus (two fingerbreadths). Patient is preferentially positioned in the semiupright or lateral position (see Fig. 201-1). Three "pops" will usually be felt as the needle penetrates the skin, the fascia, and the peritoneum.
  - Lateral approach: Enter 3 to 5 cm medial and cranial to the anterior superior iliac spine. Patient may be in the supine position or tilted slightly to the side of collection (see Fig. 201-2). At least two pops will be felt as the needle penetrates the skin and the peritoneum (fluid returns). One or two additional pops may be felt in between these two as the needle penetrates fascia before penetrating the peritoneum.
- Infiltrate the skin, subcutaneous, and other tissues down to the peritoneum with lidocaine (with or without epinephrine). Attempt to locate the peritoneum and infiltrate a slight amount

of lidocaine across the peritoneum. Again, resistance is generally felt (a pop) as the needle perforates the peritoneum.

7. Direct the 18-gauge needle (or a catheter system) either perpendicular to the skin at the selected site or at a 45 degree angle to the skin and caudally. (A 20- or 22-gauge needle may be preferred for diagnostic paracentesis to minimize subsequent leakage of ascitic fluid.) A "Z-tract" technique should used (Fig. 201-3), especially if there is tense ascites. Two alternate Z-tract techniques are described: (a) the needle is inserted just through the skin, and the skin is then pulled taut from a cranial or caudal direction, moving the needle 1 or 2 cm, before the needle is advanced through deeper abdominal structures down to the peritoneum; or (b) the needle is inserted in a caudal direction at a 45-degree angle, just through skin and subcutaneous tissue. The skin is then pulled taut in a caudal direction, pulling the needle toward a more perpendicular position. It is then inserted down

into the peritoneal cavity. The theoretical advantage of these techniques is the "self-sealing" of the needle tract when the tension on the skin is released after the procedure is completed, thus minimizing leaking of peritoneal fluid. With either method it is important to apply suction only intermittently as the needle is inserted through the deeper structures. Applying continuous suction after the needle has penetrated the peritoneum may attract bowel loops or omentum, occlude flow, and create the appearance of an unsuccessful tap, all of which increase the likelihood of bowel perforation. Insert the needle until fluid returns in the syringe. The needle can be rotated 180 degrees if peritoneal tenting is suspected because this helps enter the peritoneal cavity. If no fluid returns from an area of shifting dullness after rotating the needle, withdraw the needle to just below the skin and then redirect the needle in an area just inferior (midline approach) or just lateral (lateral approach) to the previous

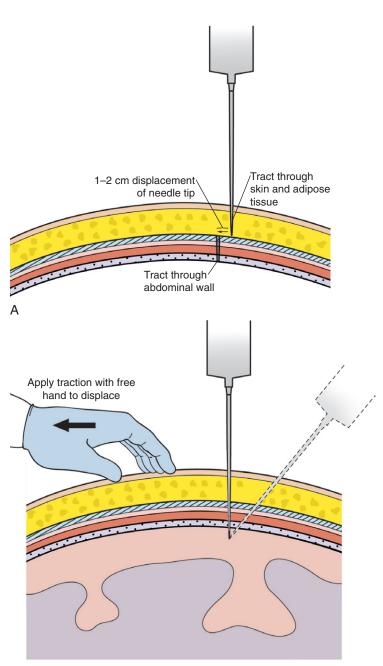

Figure 201-3 The Z-tract technique. A, Transverse view through the abdominal wall demonstrating the Z-tract. B, The needle is inserted perpendicular to the skin on the abdominal wall, which is then pulled taut or retracted a few centimeters caudad (or cephalad) by the non–needle-bearing hand (arrow). The needle is then advanced through the subcutaneous and deeper structures until it pierces the peritoneum and fluid is obtained. (As an alternative, the needle can be inserted into just the skin and subcutaneous tissue at a 45-degree angle, directed caudally. When traction is placed on the skin or the skin is pulled taut in a caudal direction, the needle will be pulled more upright, toward a position more perpendicular to the skin. The needle is then advanced downward until fluid is obtained.) When the procedure is finished, the needle is withdrawn, traction is released, and the abdominal wall layers will shift back to their natural positions to facilitate closure of the needle tract.

attempt. If still no fluid returns, another attempt can be made using a different location. If the initial attempt was made in the midline, consider another attempt in the lateral location (if not contraindicated) or in the midline 1 cm below the prior attempt. If the initial attempt was in the lateral location, consider another attempt in the midline (if not contraindicated) or 1 cm lateral to the prior attempt. If these attempts are unsuccessful, ultrasonography should be used to guide the paracentesis. Ultrasonography can be used to quantify the amount of fluid expected (1 cm³ of fluid equals 1 mL) as well as determine the direction necessary to obtain this fluid. It can also be used to make sure no vital organs are in the pathway chosen for aspiration (see Chapter 225, Emergency Department, Hospitalist, and Office Ultrasonography [Clinical Ultrasonography]).

If a catheter-over-needle system is used, advance the needle 1 to 2 mm after the flash of ascitic fluid is seen. Occlude the needle hub temporarily with a sterile gloved finger. Using the no. 11 blade scalpel, a small nick in the skin near the catheter (taking care not to cut the catheter) may facilitate passage of the catheter. Directing the needle toward a fluid-dependent position, advance the catheter over the needle, using a twisting motion, until the hub is against the skin. Gently withdraw the needle while holding the hub securely against the skin. Attach a syringe, if fluid is needed for diagnostic reasons, or the sterile IV tubing for therapeutic paracentesis.

For the Seldinger technique (catheter-over-wire system such as that used for central venous catheter insertion), advance the needle 1 to 2 mm after a flash of ascitic fluid is seen. (These are special needles tapered at the hub to facilitate advancement of the guidewire; standard hypodermics will generally not allow passage of a guidewire.) Occlude the needle hub temporarily with a sterile gloved finger, and then insert the guidewire through the hub. Insert the guidewire to the desired depth, always making sure at least several centimeters remains outside the beveled end of the hub. Holding the guidewire securely on the proximal end, remove the needle over the guidewire. After the needle tip has been removed from the skin, grasp the guidewire below the needle with sterile gloved fingers to prevent it from being pulled out of the peritoneal cavity. Using the no. 11 blade scalpel, a small nick in the skin near the guidewire (taking care not to cut the guidewire) may facilitate passage of the dilator/sheath unit through the skin. Place the dilator through the sheath to form a unit, and then advance the dilator/sheath unit over the guidewire, using a twisting motion, up to the hub. Holding the hub securely against the skin, remove the guidewire and dilator and attach a syringe to the hub, if fluid is needed for diagnostic reasons, or the sterile IV tubing for therapeutic paracentesis.

**NOTE:** When using a catheter-over-wire system, never let go completely of the proximal end of the wire. This precaution is to prevent loss of the wire into the peritoneal cavity.

8. After entry into the peritoneal cavity, fluid (usually 20 to 50 mL) should be withdrawn and collected for analysis (see Interpretation of Results section). Note the color and clarity of the fluid; normal ascitic fluid is clear and straw colored. If a therapeutic large-volume paracentesis is indicated, the needle may be attached to sterile IV tubing. This is then connected to vacuum bottles, if available, or a stopcock can be used with sequential aspiration using a 50-mL syringe. The needle may need to be repositioned to allow for continuous flow (omentum or a loop of bowel may have occluded the flow).

**NOTE:** Never reposition the needle while the tip is within the peritoneal cavity; doing so may lacerate bowel, omentum, or a blood vessel. Instead, withdraw the needle into the subcutaneous tissue, redirect the needle, and then readvance it into the peritoneal cavity. Alternatively, the patient may need to be repositioned slightly or slight pressure applied to the abdomen.

There is controversy regarding hypotension caused by a large-volume paracentesis (>4 L). Some clinicians give colloid replacement (e.g., albumin) as prophylaxis, especially in patients with cirrhosis and hypoalbuminemia; however, there is no evidence that this practice should be adopted universally and it is not recommended for procedures removing less than 6 L of ascitic fluid. After a large-volume paracentesis, there tends to be initial improvement in circulatory function; however, total paracentesis in patients with cirrhosis may cause delayed (>12 to 24 hours after the procedure) hypotension due to effective hypovolemia. Although the literature suggests this hypovolemia may be avoided by prophylactic colloid infusion, it is difficult to obtain albumin in the outpatient setting; therefore, these infusions typically have to be done in the hospital.

9. After the fluid is removed, gently remove the needle (or catheter), cover the entry site with 4 × 4 gauze pads, and apply pressure. If the wound is still leaking fluid after 5 minutes of direct pressure, consider suturing the puncture site using a mattress suture or apply a pressure dressing.

## **COMPLICATIONS**

Complications are rare during paracentesis but include the risk of the following:

- Perforation of viscus organ (e.g., stomach, small bowel, colon; rare, and tend to be self-healing)
- Lacerations of major vessels with subsequent hemorrhage
- Abdominal wall hematoma
- Infection (local or intraperitoneal)
- Persistent ascitic fluid leak
- Hypotension (e.g., vasovagal reaction, hemorrhage, reaccumulation of fluid)
- Bladder perforation

# POSTPROCEDURE PATIENT MANAGEMENT AND EDUCATION

Complications of the procedure are rare and patients are usually able to return to their normal activities after this procedure. A brief observation period of 1 hour while monitoring vital signs is appropriate. Educate the patient about signs and symptoms of complications such as those listed (e.g., hypotension, bleeding, fever, abdominal pain or distention, nausea, vomiting), and instruct him or her to call or return to the clinician's office or the emergency department if these occur. If the site continues to ooze (e.g., tense ascites), the patient should be instructed in how to change the dressings regularly. When paracentesis is performed as an outpatient procedure, plans should be made to discuss with the patient the results of any tests performed.

## INTERPRETATION OF RESULTS

Although numerous tests are possible for ascitic fluid, the key questions of whether the fluid is infected and whether portal hypertension exists can usually be answered by obtaining the following:

- Cell count and differential (usually a purple-topped or EDTA tube)
- Bacterial culture (sensitivity and yield are increased by inoculating culture bottles at the bedside; the same bottles used for blood cultures may be used)
- Concurrent serum and ascitic fluid albumin and protein (usually a red-topped tube) to calculate serum—ascites albumin gradient (SAAG; see Table 201-1), which is approximately 97% accurate for diagnosing portal hypertension

To determine if preexisting ascites has become infected, some authors suggest using the cell count as the initial screen; if values

are normal (<250/mm³), the likelihood of infection is low. If the cell count is elevated, a confirmatory culture is required, but the patient should be admitted for empiric treatment with IV antibiotics (typically a third-generation cephalosporin, such as cefotaxime, which covers 98% of the causative agents for this disorder [Escherichia coli and streptococcal species; ampicillin should be added if Enterococcus is suspected]). It is also acceptable to culture all samples, but treat empirically only when cell counts are abnormal. For the evaluation of new-onset ascites, the initial evaluation often centers around whether the etiology is portal hypertension (often due to cirrhosis) or other factors. An increased red blood cell count can also be seen in malignancy, tuberculosis, endometriosis, mesenteric thrombosis, pancreatitis, abdominal trauma, and perforated viscus.

Additional studies on ascitic fluid to determine the etiology of new-onset ascites might include Gram stain (usually not helpful because bacterial concentrations are very low unless bowel is ruptured or perforated), triglyceride level (particularly if "milky" appearance, e.g., pancreatitis), smear for acid-fast bacteria (AFB), or assay for AFB by RNA polymerase chain reaction and AFB culture. (Suspect AFB in immunocompromised patients or those who have immigrated from areas where mycobacterial diseases are endemic; AFB culture has a sensitivity of about 50%.) Chemistries that might be obtained on both serum and ascitic fluid include glucose, lactate dehydrogenase, and amylase. Table 201-1 lists some common values to assist in laboratory interpretation.

Peritoneal carcinomatosis is possible in patients with a prior history of colon, breast, gastric, pancreatic, hepatobiliary, hepatocellular, ovarian, or other cancers. Ascitic fluid should be sent for cytologic study in these patients or anyone suspected of having a malignancy.

TABLE 201-1 Ascitic Fluid Analysis				
Laboratory Test	Suggests Cirrhosis or Portal Hypertension	Suggests Inflammatory Process <sup>†</sup>		
White blood cell count (mm³)	<250	>250 (often >500 with >50% polymorphonuclear leukocytes)		
SAAG (g/dL) <sup>‡</sup>	≥1.1 suggests portal hypertension	<1.1		
Protein (g/dL) Lactate dehydrogenase (fluid/serum ratio)	<3 ~~ <0.6	>3 ≥0.6		

\*Some causes of portal hypertension: Cirrhosis, congestive heart failure (cardiac ascites), inferior vena caval obstruction or other veno-occlusive disease, Budd-Chiari syndrome (hepatic vein or inferior vena caval thrombosis), portal vein thrombosis, sarcoidosis, fulminant hepatic failure, alcoholic hepatitis, massive liver metastases, myxedema, mixed ascites.

<sup>†</sup>Some causes of inflammatory processes: Spontaneous bacterial peritonitis, malignancy, tuberculosis, pancreatitis, connective tissue disease. Nephrotic syndrome can cause ascites without an inflammatory process and SAAG < I.I g/dL.

\*Serum—ascites albumin gradient (SAAG) = [Serum albumin] — [Ascitic fluid albumin] alone is approximately 97% accurate in diagnosing portal hypertension. Increased red blood cell count can be seen in malignancy, tuberculosis, endometriosis, mesenteric thrombosis, pancreatitis, abdominal trauma, and perforated viscus.

# GASTROINTESTINAL DECONTAMINATION

Michael Zeringue • Grant C. Fowler

The overall mortality from acute poisoning is less than 1%; therefore, the challenge to clinicians is to determine which patients face serious complications from poisoning if not treated. If the decision is made to treat, activated charcoal has become the first-line treatment for most ingested toxins, especially for ingestion of a small or moderate amount. Multiple doses of charcoal are recommended by some experts, especially for toxins recycled in the enterohepatic circulation or those with long half-lives. Certain experts also add a laxative or cathartic to charcoal for more rapid elimination and to avoid constipation. Whole-bowel irrigation is a newer treatment; for most toxins, it is usually considered second-line treatment after activated charcoal. Rarely is gastric emptying (by lavage or induced emesis with substances like ipecac) recommended anymore, unless activated charcoal or whole-bowel irrigation is not available or gastric lavage or induced emesis can be performed very rapidly and will not delay administration of activated charcoal. It is rarely indicated for ingestion of corrosives or petroleum distillates because of risk of esophageal injury or aspiration. However, in certain cases, the potential benefit of removal of a highly toxic substance (e.g., benzene, pesticides) may outweigh the risk of complications. Consultation with a medical toxicologist or regional poison control center (1-800-222-1222) may help guide choice of intervention. For the sake of completeness, this chapter continues to cover techniques for gastric emptying.

#### MECHANISMS OF ACTION AND EVIDENCE

Charcoal is "activated" by the manufacturer by heating it to approximately 900° C and washing it in a stream of carbon dioxide gas or steam. This increases the surface area from 2 m²/g to greater than 2000 m²/g; consequently, a 50-g dose has the surface area of 10 football fields. When ingested, there is no modification of charcoal's structure by digestive enzymes as it passes through the stomach and intestines, nor is it absorbed across the intestinal wall. Activated charcoal binds with toxins and then passes through the gastrointestinal tract to be eliminated in the stool as a sticky black substance. As the charcoal absorbs the toxin in the intestine and passes distally, it creates a diffusion gradient. This in turn causes already absorbed toxins to diffuse back across the intestinal membrane and into the lumen; it somewhat dialyzes the intestinal blood. Thus, charcoal decreases systemic absorption of toxins by both its absorptive mechanism and its ability to form a diffusion gradient.

Charcoal has an excellent safety profile; it is even considered safe during pregnancy, in lactating women, and in the pediatric population. Although studies show a better safety profile and a more effective decrease in toxin absorption compared with lavage or ipecac-induced emesis, no significant decrease in mortality, length of hospital stay, or likelihood of clinical deterioration has been demonstrated with use of activated charcoal. In studies using a single

dose of at least 50 g of activated charcoal, there was a 47% to 21% reduction in toxin absorption when administered 30 to 180 minutes after toxin ingestion, respectively. Although the clinical benefit of activated charcoal is less clear after 1 hour, "the potential for benefit ... cannot be excluded" (Position paper, 2005).

Similarly, although studies have shown statistical significance for multidose charcoal's effectiveness in removing toxins, it has not been shown to reduce morbidity or mortality. Therefore, multidosing is usually not recommended except for a select list of drugs (see Indications). Although there is no evidence supporting their use, cathartics are added to charcoal by some experts to hasten elimination. This may be especially helpful when large doses of charcoal have been administered, which can be constipating. If cathartics are used, it should be kept in mind that there are general, as well as specific, contraindications to certain agents. In the very young and elderly, cathartics can cause very large stools, dehydration, and electrolyte abnormalities such as hypernatremia. Sorbitol, which is used as a preservative and to decrease the grittiness of charcoal, also enhances the flavor of charcoal by making it slightly sweet. It is not absorbed and therefore encourages water secretion into the lumen, which in turn stimulates bowel peristalsis; however, it can cause severe cramping, hypotension, and vomiting and increase the risk of pulmonary aspiration. Sorbitol dosing in children is not clearly established and, therefore, if premixed with charcoal, may not be appropriate. Magnesium, another cathartic, is contraindicated in patients with hypermagnesemia, myasthenia gravis, renal insufficiency, or cardiac arrhythmias. Sodium-based cathartics should be avoided in patients with severe hypertension, renal failure, or congestive heart failure. Mineral oil- or other oil-based cathartics should not be used because of risk of aspiration.

Whole-bowel irrigation uses the infusion of polyethylene glycol (PEG) electrolyte solution (the same as used for preparation for colonoscopy) at a rate faster than normal for a bowel preparation. PEG infusion works by decreasing enteric transit time, thereby reducing toxin contact time with the intestinal wall and decreasing absorption. Whole-bowel irrigation has an advantage over cathartics in that it does not cause electrolyte disturbances because it does not create an osmotic differential across the intestinal membrane. Whole-bowel irrigation is especially useful for ingestions of toxins not absorbed by charcoal (e.g., iron, lithium, heavy metals), sustained-release or enteric-coated pills (if multidosing charcoal is not indicated), or illegal drug packets. Studies have found whole-bowel irrigation to decrease toxin bioavailability by up to two thirds.

Gastric lavage was at one time the chosen method to decontaminate the intestinal tract. However, in 1997, the American Academy of Clinical Toxicology/European Association of Poisons Centres and Toxicologists made the following statement: "Gastric lavage should not be considered unless a patient has ingested a potentially life-threatening amount of a poison and the procedure

can be undertaken within 60 minutes of ingestion. Even then, clinical benefit has not been confirmed in controlled studies.' Despite this knowledge, gastric lavage has not been completely abandoned. Some authorities believe that there are not enough data to direct decisions on all patients with potentially fatal ingestions. They believe that this lack of evidence should not lead to the discontinuance of gastric lavage, a logical, relatively safe, and inexpensive procedure. Gastric lavage can be considered when the substance ingested has high evidence of toxicity or risk of fatality or other supportive modalities are inadequate or unavailable. It is most effective for massive ingestions of solutions or small tablets, and is not as effective for large tablets or mushrooms, which may obstruct the orogastric tube when attempting to aspirate (see Indications and Contraindications). If performed within 5 minutes, 90% of ingestants are recovered, compared with 45% at 10 minutes, 30% at 19 minutes, and 8% at 60 minutes. Gastric lavage can also be used to evaluate gastric contents for poison or to administer charcoal. Specialized lavage (neutralizing) solutions may be indicated (after consultation with a toxicologist or poison control center) for ingested fluoride, formaldehyde, iodine, iron, or oxalic acid.

Syrup of ipecac has two pharmacologically active alkaloids, emetine and cephaeline, which stimulate both the gastric mucosal sensory receptors and the chemoreceptor trigger zone in the brain; given soon after toxin ingestion, ipecac can partially evacuate the gastric contents. However, there is no clear evidence for improved outcomes and its use is associated with the increased risks of pulmonary aspiration and delayed administration of activated charcoal. Therefore, like gastric lavage, induced emesis is no longer routinely recommended in poisoned patients. In fact, American poison centers recommended ipecac in only 0.6% of cases in 2002. That said, it may be considered in an alert patient who has ingested the toxin less than 60 minutes ago and for whom activated charcoal, whole-bowel irrigation, and gastric lavage are not indicated or available. Such may be the case at home or in the prehospital setting.

## **INDICATIONS**

#### **Activated Charcoal**

- Most toxic substances
- Toxins metabolized by the liver and secreted into the bile
- Toxins that are recycled in the enterohepatic circulation and have long half-lives

#### **Multidose Activated Charcoal**

- Toxins that are recycled in the enterohepatic circulation and have long half-lives, including some sustained-release or entericcoated preparations
- Amitriptyline
- Carbamazepine
- Dapsone
- Diazepam
- Digoxin
- Doxepin
- PhenobarbitalPhenytoin
- Piroxicam
- Quinine
- Salicylates
- Tricyclic antidepressants
- Theophylline

#### Whole-Bowel Irrigation

- Life-threatening or serious ingestion not effectively removed by activated charcoal
- Medications with delayed absorption or sustained-release or enteric coatings

- · Ingested packets of illicit drugs
- Iron (often seen on flat-plate radiograph)
- Lithium
- Heavy metals
- Activated charcoal not indicated or available

## **Gastric Lavage**

## Substances Able to Be Neutralized (after Consultation with Toxicologist or Poison Control Center)

- Fluoride
- Formaldehyde
- Iodine
- Iron
- Oxalic acid

## Substances with High Risk of Morbidity or Mortality

- Beta blockers
- Calcium channel blockers
- Chloroquine
- Colchicine
- Cyanide
- Heavy metals
- Heterocyclic antidepressants
- Iror
- Paraquat
- Salicylates
- Selenious acid

#### Substances Poorly Absorbed by Activated Charcoal

- Iron
- Lithium
- Heavy metals
- Toxic levels of alcohol

#### **Substances That Form Concretions**

- Sustained-release or enteric-coated preparations
- Iron
- Phenothiazines
- Salicylates

## Substances with Ineffective or No Antidotal Therapy Available

- Colchicine
- Paraguat
- Selenious acid

## **Induced Emesis (Syrup of Ipecac)**

- Conscious, alert patient
- Potentially toxic dose of poison ingested within 60 minutes
- Activated charcoal, whole-bowel irrigation, gastric lavage are not indicated or available

## **CONTRAINDICATIONS**

## **Activated Charcoal**

- Unprotected airway
- Comatose or convulsing patient (unless the airway can be protected)
- Recent gastrointestinal surgery
- Ingestion of corrosive agent and endoscopy is planned
- Bowel obstruction or ileus
- Recent use of anticholinergic or antiperistaltic drugs
- Substances not absorbed by activated charcoal such as iron, lithium, lead, and other heavy metals, cyanide, acids, alkalis, alcohol, boric acid, petroleum distillates, pesticides

## Use of Cathartic with Activated Charcoal

- Ingestion of a toxin that already causes diarrhea
- Electrolyte abnormality
- Debilitated or elderly patient who may not tolerate
- Children younger than 5 years of age
- Intestinal obstruction
- Severe dehydration
- Mineral oil
   or other oil-based cathartics

#### **Use of Sodium-Based Cathartics**

- Severe hypertension
- Renal failure
- Congestive heart failure

#### Use of Magnesium-Based Cathartics

- Hypermagnesemia
- Myasthenia gravis
- Renal failure
- Abnormally slow heart rate

## Whole-Bowel Irrigation

- Unprotected airway
- Abnormal gastrointestinal anatomy (e.g., strictures, anomaly) or recent gastrointestinal surgery
- Bowel perforation, obstruction, or ileus
- Ingestions of substances that cause an ileus (e.g., anticholinergics, antiperistaltics, opioids)
- Gastrointestinal bleed
- Vomiting
- Patient unable to remain sitting on toilet (relative contraindication)

## **Gastric Lavage**

- Depressed mental status or inactive or diminished airway reflexes (unless airway can be protected)
- Active or substantial antecedent vomiting
- Abnormal pharyngeal or upper gastrointestinal anatomy
- Ingestion of corrosive agents
- Coagulopathy
- Large pills or particles (e.g., mushrooms)
- Large or sharp foreign body
- Nontoxic or minimally toxic ingestion
- Significant risk if aspirated (e.g., low-viscosity hydrocarbon or petroleum distillates)
- More than 60 minutes after ingestion
- Infants and neonates

#### **Induced Emesis**

- Depressed mental status
- Ingestion of corrosive agents
- Low-viscosity petroleum distillates or hydrocarbons (high risk of aspiration if vomiting occurs)
- Repeated vomiting would pose a health danger (e.g., recent gastrointestinal surgery, elderly or debilitated, third-trimester pregnancy, severe hypertension)

#### **EQUIPMENT**

- Equipment necessary for the clinician to follow universal blood and body fluid precautions (e.g., eye protection, mask, gloves, gown)
- Nasogastric tube (optional for administration of activated charcoal [i.e., for the patient who refuses to swallow charcoal], but use at least a 16-Fr diameter in adults for activated charcoal. A 10- to 12-Fr tube can be used for whole-bowel irrigation in

anyone older than 1 year of age; infants can usually tolerate an 8-Fr tube.) An orogastric tube may be used instead for gastric lavage.

- 2% viscous lidocaine gel, or benzocaine; phenylephrine decongestant nasal spray for nasogastric tube insertion
- 50-mL tube syringe (Toomey)
- Towel or surgical Chux for covering patient's clothing
- Paper tissues
- Emesis basin
- Suction tube with vacuum generator
- Endotracheal tube with cuff for obtunded patients or those with an altered mental status or at risk of altered mental status or convulsions because of what they have ingested. Intubation should also be considered to protect the airway in patients who have ingested hydrocarbons.
- Intravenous (IV) antiemetics (e.g., promethazine); optional, but must avoid sedating dose

#### **Activated Charcoal**

Activated charcoal (1 g/kg): Flavored versions (e.g., cherry) are available. Preparations are also available containing sorbitol, which is an artificial sweetener and may make the charcoal slurry or solution seem less gritty and more palatable; however, sorbitol is also a laxative.

## Whole-Bowel Irrigation

Use 4 to 8 L of balanced PEG electrolyte solution (e.g., Colyte, GoLYTELY, MoviPrep) at body temperature for whole-bowel irrigation.

## **Gastric Lavage**

Use 3 L of normal saline at body temperature for gastric lavage.

#### **Open-System Gastric Lavage**

- Large-diameter gastric tube with extra holes cut near the tip (A 32- to 50-Fr orogastric tube is recommended for adults; a 16- to 32-Fr orogastric tube is recommended for children. Small children can generally accommodate a 24-Fr tube. Nasogastric tubes are discouraged (traumatize nasal mucosa and are too small for effective aspiration of gastric contents)
- Y-connector and clamp, with or without suction apparatus, and tubing

#### Closed-System Gastric Lavage

The EASI-LAV kit (Kimberly-Clark/Ballard Medical Products, Roswell, Ga) is an example of a closed system. It includes a fluid bag and tubing, a waste bag and tubing, a double-barrel syringe mechanism, a gastric tube, and a sample cup.

#### **Induced Emesis**

Use syrup of ipecac (2%), usually provided in 1-ounce bottle.

## PREPROCEDURE PATIENT PREPARATION

The patient or representative should know what to expect when activated charcoal is administered, especially if multiple doses will be needed or a cathartic will be used. The patient should be aware that if he or she is unwilling or refuses to swallow the charcoal, a nasogastric tube will be inserted. Likewise, a nasogastric tube will be inserted for whole-bowel irrigation, and a larger nasogastric or orogastric tube inserted for gastric lavage. The patient or representative should also know what to expect if whole-bowel irrigation, gastric lavage, or induced emesis will be performed. IV antiemetics may be used to minimize nausea when any of these procedures are

performed (except, of course, induced emesis, unless vomiting is prolonged). Although administration of activated charcoal, whole-bowel irrigation, gastric lavage, or induced emesis is typically performed as an urgent or emergent procedure and most hospitals do not require written informed consent, the risks, benefits, indications, and any possible alternatives should be explained to the patient or representative.

Insertion of a nasogastric or orogastric tube can be very distressing for the conscious patient (see Preprocedure Patient Preparation section in Chapter 203, Nasogastric and Nasoenteric Tube Insertion, for additional information).

Airway protection with a cuffed endotracheal tube (see Preprocedure Patient Preparation section in Chapter 213, Tracheal Intubation) is very important for a patient whose level of consciousness is depressed, whose airway-protective reflexes are diminished, or who is otherwise in danger of aspiration (e.g., altered mental status, obtunded, unconscious, convulsing). For activated charcoal, whole-bowel irrigation, and induced emesis the patient should be upright or semiupright. For whole-bowel irrigation, the patient should optimally be capable of sitting on the toilet for a few hours. For gastric lavage, the patient should be positioned in the left lateral recumbent or decubitus position with the head lowered approximately 10 degrees (Trendelenburg position). These positions decrease the risk of aspiration should vomiting occur.

## **TECHNIQUE**

## **Activated Charcoal**

- 1. If the patient is unable, unwilling, or refuses to swallow the charcoal, place at least a 16-Fr nasogastric tube in adults and confirm its placement before administration of any fluids (see Chapter 203, Nasogastric and Nasoenteric Tube Insertion). Aspirated gastric contents can be saved or sent for analysis if the toxin is unknown. If the patient is unable to protect his or her airway, endotracheal intubation should be considered (see Chapter 213, Tracheal Intubation). (The absence of blinking after touching the eyelashes is strong evidence of inability to protect the airway from vomitus.) Intubation should also be considered in any patient who has ingested a central nervous system antidepressant or any substance that can cause altered mental status or seizures. The patient should not undergo endotracheal extubation until 4 hours after the last dose of charcoal is administered.
- 2. Charcoal can be ordered as capsules, tablets, powder, or oral suspension/solution. However, with an acute toxin ingestion, only powder mixed with water or a premixed oral suspension or solution, with or without a cathartic, is recommended. Olderstyle preparations or suspensions were gritty and, although they had no taste, were unpleasant to swallow. Newer-style preparations dissolve completely when added to water and form a solution. Flavored versions are also available.
- Optimally, administration of charcoal should occur within the first hour of ingestion.
- 4. Powder comes in doses of 15 to 500 g. It should be mixed in water to achieve a slurry.
- 5. It has become standard practice to administer 50 to 100 g of charcoal for an adult and 1 g/kg (maximum 50 g) for a child.
- 6. An IV antiemetic can be administered to decrease vomiting/ nausea. Avoid a sedating dose.
- 7. In adults, activated charcoal can be mixed with 70% sorbitol (1 g/kg) or 10% solution of magnesium citrate (typically given as 250 mL for adults).
- 8. For multidose charcoal treatment, follow the initial dose of 50 to 100 g with 25 to 50 g every 4 hours, possibly alternating with and without a cathartic. (A cathartic is not used with each dose to avoid side effects such as very large stools, dehydration, and electrolyte abnormalities.) Monitor the patient between doses to

- verify the presence of bowel sounds and to confirm the absence of distention or an ileus.
- The nasogastric tube should be removed before extubation to avoid aspiration of charcoal as the nasogastric tube is being removed.

## Whole-Bowel Irrigation

- 1. Place the nasogastric tube and confirm its placement before administration of any fluids (see Chapter 203, Nasogastric and Nasoenteric Tube Insertion). Consider endotracheal intubation in the patient who may become obtunded or sedated or may convulse. A 10- to 12-Fr tube can be used for whole-bowel irrigation in anyone older than 1 year of age; infants can usually tolerate an 8-Fr tube.
- Introduce PEG electrolyte into the nasogastric tube at an initial rate at 25 mL/kg/hr. Increase the rate, depending on patient tolerance, while also trying to avoid vomiting and abdominal distention. Adults often tolerate greater than 3 L of PEG per hour.
- Continue treatment until the patient passes the ingestant or clear rectal fluid.
- 4. The patient should be continually assessed for any signs of airway compromise, ileus, or abdominal distention. If significant abdominal distention occurs or there is a loss of bowel sounds, irrigation should be held for 30 to 90 minutes and the patient reassessed. If bowel sounds have returned, irrigation can be resumed at a reduced rate. If the patient tolerates irrigation at the reduced rate, and the clinical status improves, it can be continued at this rate or possibly increased gradually as tolerated.

## **Gastric Lavage**

Lavage can be performed with either an open or a closed system. Open systems are generally more time-consuming and potentially messy, but they are also less expensive. Open systems use either an active or a passive process.

For passive lavage, once the intragastric tube is in place, it is merely used as a siphon. Active lavage uses a syringe to generate pressure as well as to aspirate and irrigate the stomach. A large syringe is used to inject and remove the fluid from the stomach through the gastric tube. This syringe must be disconnected from the tube to be filled and emptied after each lavage cycle. Alternatively, two tubes may be inserted, one in each nostril. One tube is used as the input port and the other as the output port.

Closed systems are available prepackaged in commercial kits, self-contained and easy to use. They generally provide more protection to the health care provider. Closed systems usually apply an active lavage process. A well-tested closed and active system, EASI-LAV, uses a double-barrel syringe with automatic two-way valves. The syringe remains attached to the gastric tube. Its stroke volume of 125 mL allows for rapid fluid movement and the creation of fluid turbulence, resulting in fast, easy removal of toxic substances or clots.

Again, specialized lavage solutions may be indicated (after consultation with a toxicologist or poison control center) if the ingested substance is fluoride, formaldehyde, iodine, iron, or oxalic acid.

- Premeasure and mark the length of the tube needed by estimating the distance from the nose, around the ear, and down to the mid-epigastrium. To prepare the tube, larger holes may be cut in the end of the tube to accommodate larger pill or charcoal fragments.
- 2. In most cases, nasal intubation for gastric lavage is discouraged; it may cause injury to the mucosa and turbinates and severe hemorrhage, and the diameter is usually not large enough to aspirate particles effectively. However, if the tube is to be inserted nasally, spray both nostrils with the decongestant nasal spray and do not use larger than an 18-Fr tube. Lidocaine

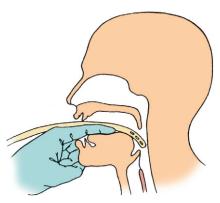

Figure 202-I Orogastric tube insertion.

gel may be placed into the tube syringe and slowly instilled into one nostril. Ask the patient to "sniff and swallow," if he or she is able to do this. (See the procedure for nasogastric tube insertion in Chapter 203, Nasogastric and Nasoenteric Tube Insertion.) Consider endotracheal intubation in the patient who may become obtunded or sedated, or may convulse.

- 3. For orogastric tube insertion, if the patient is alert, spray the posterior pharynx with topical benzocaine or Cetacaine spray. Position the patient's head so that it is flexed as far forward as possible and, while ensuring against being bitten (i.e., bite block), insert your gloved index and middle fingers over the base of the patient's tongue. Guide the lubricated orogastric tube over the dorsum of your fingers as the patient swallows (Fig. 202-1). If the patient gags, advance the tube immediately after gagging. Advance the tube to the previously measured distance marked on the tube.
- 4. Confirm intragastric tube placement initially by auscultating the stomach while introducing air with the syringe. Verify the final placement by aspirating and confirming gastric contents. It is critical to avoid infusion of fluids until tube placement is confirmed. The aspirate may be sent for toxicologic analysis. Secure the tube with tape.

#### A. Open-System Procedure

See Figure 202-2.

- 5a. Introduce the normal saline at a rate of 1 to 2 mL/kg per cycle from an IV bag or large syringe attached to the tube with a Y-connector in the proximal circuit.
- 6a. During saline infusion, clamp the efferent drainage arm. After instilling approximately 150 to 200 mL (50 to 100 mL in children), clamp the afferent reservoir arm. Then open the drainage arm to allow gravity to siphon and evacuate the stomach contents. Intermittent suction may be applied to facilitate gastric emptying. Manual agitation of the stomach by gentle massage of the upper abdominal wall will enhance recovery of gastric contents.
- 7a. With an active system, use a syringe or vacuum suction equipment, instead of gravity, to irrigate and evacuate the gastric contents.
- 8a. Continue gastric irrigation until at least 3 L of lavage have been used and the return is clear on visual inspection.
- 9a. After gastric lavage has been completed, a slurry of activated charcoal can be used (see earlier sections for Indications and Contraindications for charcoal). It may be administered cleanly by adding 50 to 100 g (1 g/kg) of the powder through an opened upper corner of a partially full, hanging IV bag. Infuse this mixture through the orogastric circuit with the efferent arm clamped. Either the charcoal can be allowed to pass through the gastrointestinal tract, or additional saline lavages can be performed until the slurry is cleared of charcoal.
- 10a. When the procedure is completed, clamp or pinch the gastric tube during removal to prevent contaminating the lung with charcoal or gastric contents. If repeated doses of charcoal are deemed necessary, the large tube may be replaced with a standard, smaller nasogastric tube. In the obtunded, intubated patient, leave the endotracheal tube in place for at least 15 minutes after gastric tube removal to prevent aspiration. Confirm adequate spontaneous respirations and oxygenation by pulse oximetry before removing the endotracheal tube.

## **B.** Closed-System Procedure

The procedure described here uses the EASI-LAV system (Fig. 202-3).

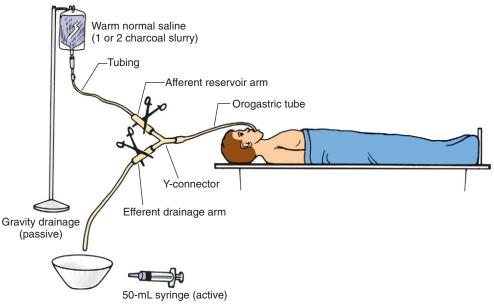

Figure 202-2 Open gastric lavage system assembly with components.

**Figure 202-3** Performing gastric lavage with the closed double-barrel syringe system. (From Haynes JH: Gastric lavage for serious poisonings. Fam Pract Recert 14:45, 1992. Courtesy of Kimberly-Clark/Ballard Medical Products, Roswell, Ga.)

- 5b. Hang a waste bag from the bed. Close the sampling port clamp and cap. Close the fluid bag clamp and fill the fluid bag with normal saline solution. You can rest the fluid bag on the countertop when sealing it. Finally, hang the fluid bag from an IV pole.
- 6b. Next, evaluate the already inserted orogastric tube. Bending or kinking of the gastric tube may cause malfunction of the system. Ensure airway protection.
- 7b. Advance both syringe plungers to the fully forward position. Attach the syringe to the gastric lavage tube and pinch the retaining collar in place.
- 8b. Reconfirm proper tube placement, initially, by locking the red output plunger in the fully forward position and pumping the blue input plunger alone while listening for air bubbles in the stomach. Again verify correct placement finally by aspirating gastric fluid and confirming that it is indeed gastric fluid.
- 9b. Next, attach the blue tubing connection from the fluid bag to the blue input port on the syringe. Attach the red tubing connection from the waste bag to the red output port on the syringe. Ensure that both syringe plungers are in the fully forward position. Always leave the blue input plunger forward when not in use or fluid will flow into the patient's stomach. Open the clamp on the fluid bag.
- 10b. To empty the stomach, first confirm that the clamp on the waste bag line is opened. Next, pump the red output plunger alone until resistance is encountered or no return is obtained. To avoid mucosal injury, never pull the red plunger against stiff resistance.
- 11b. Lock the red output plunger in the forward position by pushing the plunger completely forward and rotating it clockwise 90 degrees. Prime the system by pumping the blue input plunger three times to partially fill the stomach.
- 12b. Unlock the red output plunger by rotating it 90 degrees counterclockwise. Perform the lavage as follows (see Fig. 202-3):
  - a. Grasp both plunger handles, pull back, and then push forward. This will wash out and empty the stomach.
  - b. Perform this lavage three times.
  - c. With the blue input plunger fully forward, pump the red output plunger three times (or less, if resistance is met). Repeat steps 11b and 12b(a), 12b(b), and 12b(c) until the gastric return fluid is clear.
- 13b. To administer charcoal (see earlier sections for Indications and Contraindications), the following procedure is effective:
  - a. Lock the red output plunger in the forward position by pushing it completely forward and rotating it clockwise 90 degrees.
  - b. Pour charcoal into the fluid bag and reseal the bag.
  - Lavage fluid (50 to 75 mL) may be added to thin the slurry and to speed up the administration.
  - d. Pump the blue input plunger until all of the charcoal is in the stomach.

#### **Induced Emesis**

- The patient should be in the upright or semiupright position as the ipecac is administered. The alert patient should be told that he or she may rapidly experience nausea and vomiting and that it will soon pass.
- 2. Adolescents or adults can be given 15 to 30 mL of syrup followed by 240 mL of water. Children 6 to 12 months of age should be given 5 to 10 mL of syrup of ipecac followed by 120 to 240 mL of water. Children 1 to 12 years of age should be given 15 mL of syrup followed by this same amount of water.
- 3. The dose may be repeated in all age groups if emesis does not occur in 20 to 30 minutes.

## **COMPLICATIONS**

The main complications of activated charcoal administration are aspiration, intestinal obstruction, and electrolyte imbalances or dehydration from cathartic use. Aspiration is prevented by following the patient's alertness and gag reflexes as he or she is ingesting the activated charcoal, or by endotracheal intubation. Anticholinergic and antiperistaltic drugs should not be administered around the time of activated charcoal administration because they slow down gastrointestinal transit time and increase the risk of bezoar formation.

Caution should be taken when giving a cathartic with activated charcoal. Cathartics should be withheld in any patient who has ingested a toxin that may itself already cause diarrhea. Also, they should not be given to children younger than 5 years of age. Cathartic-induced hypernatremia is a serious side effect that has been reported in young children. Magnesium should not be administered in patients with hypermagnesemia, myasthenia gravis, an abnormally slow heart rate, intestinal obstruction, or kidney failure. Finally, cathartics are not recommended with every dose of multidose charcoal.

Pulmonary aspiration with subsequent chemical pneumonitis can be devastating complications of gastric lavage or induced emesis. In one study, the incidence of pneumonitis was found to be 56% with lavage, compared with 28% with induced emesis. It is less likely with whole-bowel irrigation. Such risk can be minimized by proper patient positioning and observing the patient closely. Laryngospasm and resultant hypoxia are possible complications of any aspiration. Risks versus benefits must be considered when performing any of these procedures.

Mucosal injury or perforation of the upper gastrointestinal tract is also a possible complication of nasogastric or orogastric intubation or gastric lavage. Up to 50% of patients will complain of nausea, gassiness, mild discomfort, or distention with whole-bowel irrigation; however, these symptoms do not mandate discontinuation of the procedure.

Fluid and electrolyte disturbances are possible with gastric lavage; these are more common when water is used instead of saline. Risk of hypothermia can be minimized by using body-temperature PEG or saline. Cardiac dysrhythmias, due to aspiration or otherwise, are possible complications of gastric lavage. Other possible complications are the same as for nasogastric tube insertion (see Chapter 203, Nasogastric and Nasoenteric Tube Insertion). The most common complications for induced emesis with ipecac syrup are diarrhea, lethargy/drowsiness, and prolonged (>1 hour) vomiting.

#### **PATIENT EDUCATION GUIDES**

See the sample patient education form available online at www. expertconsult.com.

## **CPT/BILLING CODE**

91105 Gastric intubation, and aspiration or lavage for treatment (e.g., for ingested poisons)

## **ICD-9-CM DIAGNOSTIC CODES**

NOTE: Most of these codes need a specific fourth digit.

- 960 Poisoning by antibiotics
- 961 Poisoning by other anti-infectives
- 962 Poisoning by hormones and synthetic substitutes
- 963 Poisoning by primarily systemic agents
- 964 Poisoning by agents primarily affecting blood constituents

# NASOGASTRIC AND NASOENTERIC TUBE INSERTION

Yong Sik Kim

Nasogastric intubation (nasogastric tube insertion) is a common procedure performed in the hospital, emergency department, and office settings. The nasogastric tube was initially developed for gastric feeding in 1760. The indications were expanded to gastric lavage in the case of poisoning in the early 1800s. One current design, by Dr. Levin, became available in 1921 and soon became popular for preventing intraoperative and postoperative gastric distention. In the 1960s, improved technology allowed the manufacture of a double-lumen tube, which later developed into special soft tubes made of polyurethane and silicone. These tubes are also very thin and have a noncomplicated, smooth surface, useful characteristics for prolonged nasoenteric feeding.

A nasogastric tube can be used for either diagnostic or therapeutic purposes. The Levin nasogastric tube is a firm, straight, single-lumen tube with multiple distal side ports, and is used predominantly for diagnostic aspiration or to instill materials into the stomach. Unfortunately, even when low-flow-rate suction is applied to a Levin tube, or if it is applied for a very long time, the lumen frequently becomes occluded with gastric mucosa, and this can damage the gastric mucosa. In contrast, the Salem nasogastric sump tube is a double-lumen tube. The second lumen, or vent lumen, is smaller than the main suction lumen and runs alongside the larger lumen, providing a low level of continuous airflow to the stomach. This airflow prevents the main lumen from becoming occluded by gastric mucosa when suction is applied, thereby minimizing the risk of damage. The blue "pigtail" on the Salem sump is an extension of this vent lumen (Fig. 203-1). Similar to the Levin tube, the Salem sump has multiple distal side ports. Antireflux valves are available to prevent gastric contents from leaking out of the vent lumen and multiport adapters are available for the proximal end so that the same tube can be used for feeding, irrigating, suctioning, or medicating. Even though the Levin tube is still manufactured and available, hospitals predominantly stock the Salem sump tube because it can be used for most applications and is more effective and safer.

Salem sump tubes are usually clear, yet radiopaque, and made of polypropylene or Silicone, whereas Levin tubes are available in various versions, including red rubber and clear polypropylene. Levin tubes can be either radiopaque or radiolucent. Although both can be used for short-term (up to 4 weeks) gastric or nasoenteric feeding, most facilities now have the longer and smaller-diameter polyurethane tubes specially designed for this purpose. These softer tubes (especially softer at body temperatures) usually have a tungsten-weighted tip or balloon near the tip to facilitate passage beyond the pylorus. They may also have a stiffening wire or stylet available for use during insertion; many have also been designed to resist collapse when checking the gastric residual (Fig. 203-2). Other styles of tubes include those equipped with a large esophageal balloon that can be used to tamponade a bleeding

esophageal lesion (e.g., esophageal varices). Larger gastric tubes are also available for gastric lavage (see Chapter 202, Gastrointestinal Decontamination).

#### **ANATOMY**

The nasal cavity is lined by highly vascularized and innervated mucosa and continues posteriorly as the nasopharynx. Within the nasal cavity are the superior, inferior, and middle nasal conchae (turbinates), which divide the cavity into four passages (Fig. 203-3), the meatuses. Traditionally, the nasogastric tube is inserted blindly through middle and inferior meatuses. Beyond the nasal cavity, the pharvnx extends from the base of the skull to the inferior border of the cricoid cartilage. It is divided into three parts: the nasopharynx, oropharynx, and laryngopharynx (hypopharynx). The nasopharynx gives rise to the oropharynx at the level of the soft palate, which then gives rise to the laryngopharynx (hypopharynx) at the superior border of the epiglottis (see Chapter 77, Nasolaryngoscopy, Fig. 77-6). The laryngopharynx becomes continuous with the esophagus at the inferior border of the cricoid cartilage. The posterior part of the upper nasopharynx is surrounded by the cribriform plate and the body of the ethmoid and sphenoid bones, which can easily be broken by a traumatic blow to the midface, resulting in a maxillofacial or basilar skull fracture. Such fractures can create a route into the cranial vault, which is a prerequisite for one of the most disastrous complications of inserting a nasogastric tube, intracranial intubation. This can result in brain damage or death. Therefore, placement of a nasogastric or nasoenteric tube in a patient with a possible skull or maxillofacial fracture should be avoided, if possible (an orogastric route may be a better option).

Beyond the laryngopharynx and the larynx, the trachea lies anterior to the esophagus at the level of the cricoid bone and is supported by fibrocartilaginous tracheal rings. The superior aperture is covered by the epiglottis of the larynx during swallowing.

The anatomy also confers the ability to estimate the length of tube that should be inserted. Because the median distance from the anterior aspect of the nasal septum to the cricopharyngeus muscle (tracheoesophageal junction) is about 8 inches, and the esophagus is on average about 10 inches long, and given that the tip of a nasogastric tube should lie 4 inches below the gastroesophageal junction when in place, the nasogastric tube should ideally be secured at the 20- to 24-inch mark at the nasal vestibule. Alternatively, the distance can be approximated by holding the tube up to the patient's ear and across to the nose, and then extending it to 6 inches below the xiphoid process (8 to 10 inches for a nasoenteric tube; this is described later in the Technique section).

The anatomy of children regarding the insertion of a nasogastric tube warrants a special note. Children have larger tonsils and adenoids, and their tongues are large compared to adults and may

**Figure 203-2** Feeding nasogastrostomy tube with weighted, radiopaque tip. (COMPAT Nasogastric Tube, courtesy of Nestlé Nutrition, Minnetonka, Minn.)

push into the oropharynx, all of which can hamper the insertion of a tube. At the same time, these tissues are soft and easily injured, thereby increasing the risk of bleeding with nasogastric intubation. Limiting the size of the tube to the smaller sizes of the nostrils and nasal cavity in children usually minimizes the difficulty with insertion, despite these anatomic differences.

#### **INDICATIONS**

## **Therapeutic**

- Drainage of gastric contents/gastric decompression. Examples: small bowel or gastric outlet obstruction, paralytic ileus, upper gastrointestinal bleeding, refractory vomiting, severe pancreatitis with obstruction, gastric lavage (for drug overdose), prevention of aspiration, or before diagnostic peritoneal lavage or pericardiocentesis.
- Instillation of feedings or medications for patients unable to take by mouth. Examples: antacids, nutritional supplements, and activated charcoal for drug overdoses.

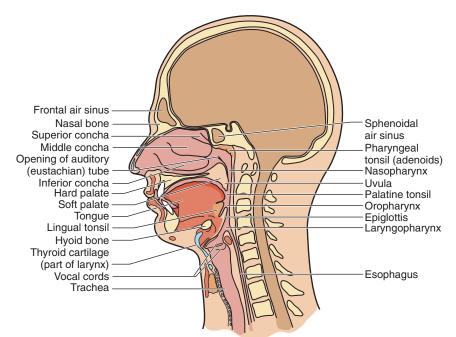

## **Diagnostic**

- Sampling gastric contents. Examples: gastrointestinal bleeding and mycobacterial infection.
- Instillation of diagnostic agents. Examples: radiopaque contrast media for delineation of a transdiaphragmatic hernia or an abdominal radiologic procedure with air to assess for an intraperitoneal perforation.
- Radiologic procedure. *Example:* to visualize the stomach on chest radiography for assessment of a diaphragmatic hernia.

#### **CONTRAINDICATIONS**

All the following contraindications are relative.

- Facial fractures, especially midface, or basilar skull fractures with possible cribriform plate injuries (may result in intracranial intubation; orogastric intubation may be a better option)
- Esophageal obstruction, strictures, or a history of alkali ingestion (increases the possibility of esophageal perforation)

**Figure 203-3** Pharyngeal anatomy: sagittal section of the head and neck. (From Thibodeau C, Patton KT: Structure and Function of the Body, 11th ed. St. Louis, Mosby, 2000.)

- Esophageal varices (may lead to rupture and uncontrollable hemorrhage)
- Comatose patients without protected airways (increases the risk of aspiration)
- Penetrating neck wounds in the awake trauma victim (gagging might stimulate increased bleeding from the wound)
- Choanal atresia
- Recent oropharyngeal, nasal, or gastric surgery
- Zenker's diverticulum
- Percutaneous endoscopic gastrostomy tube indicated (see Chapter 200, Percutaneous Endoscopic Gastrostomy Placement and Replacement).
- Severe coagulopathy (orogastric intubation may be a better option)
- Tube feeding in patients with advanced dementia (there is little evidence that the outcome will be improved)

## **EQUIPMENT AND SUPPLIES**

- Gloves, mask, goggles, and an impervious gown
- Towel or surgical Chux for covering patient's clothing
- Paper tissues
- Emesis basin
- Nasogastric tube (For adults, use a 16- or 18-Fr Salem sump [with antireflux valve, if possible] or Levin tube. Use 10-Fr tube for children.) For nasoenteric feeding tubes (5 to 12 Fr), see Table 203-1. Larger tubes (12 Fr) should be used for shorter periods because they are less comfortable and more likely to become occluded than smaller tubes (5 to 8 Fr).
- Tincture of benzoin
- Hypoallergenic tape (e.g., Hy-Tape), NG Strip, or Tube Guard
- Stethoscope
- Large (60-mL) syringe with catheter tip (Toomey)
- Suction equipment
- Cup of water with drinking straw
- Decongestant such as phenylephrine (0.25% to 2%) spray (Neo-Synephrine, Vick's) or oxymetazoline hydrochloride 0.05% spray (Afrin, Neo-Synephrine 12 hour)
- Water-soluble lubricant gel (Surgilube) or 2% lidocaine gel (Xylocaine Jelly)
- Topical anesthetic spray such as benzocaine (Hurricaine) or tetracaine hydrochloride (Cetacaine), or both. Topical cocaine is an option, and it works as both a decongestant and anesthetic. However, its use may be a problem if the patient has to undergo drug testing. In addition, purchase and storage by clinician or hospital requires significant record-keeping, and may increase the risk of theft.
- Laryngoscope for difficult insertions
- pH indicator strips with 0.5 gradations or paper with a range of 0 to 6 or 1 to 11
- Soft nasal trumpet airway (optional)

## PREPROCEDURE PATIENT PREPARATION

Although the insertion of a nasogastric tube is a common and fairly simple procedure, serious complications can occur. The risk for complications can be minimized by taking a few precautions: obtain-

ing the full cooperation of the patient, informing the patient carefully at each step of the process, using a decongestant and local anesthesia for the nasal and retropharyngeal mucosa, premeasuring and marking the length of the tube needed for insertion, using gentle technique during insertion, and carefully confirming that the tube is in the proper position before use.

Insertion of a nasogastric tube is considered by many patients to be one of the most uncomfortable and distressful procedures they have ever experienced. Although most hospitals do not require written informed consent, the risks, benefits, indications, and any possible alternatives should be explained to patients. Even with the use of decongestants and anesthetics, patients should be prepared for some discomfort. The unpleasant nature of the procedure should not be minimized.

Patients should know that their eyes may water and they may have some tearing. They may have an intense tickling sensation or an urge to sneeze. During insertion, they may experience a gagging sensation. Swallowing rapidly will minimize this response and shorten the total length of the procedure. At some point during the procedure, they will probably be asked to assist by sniffing or later by swallowing. To help them swallow, give them a glass of water and a straw. If they are not able to swallow, if they will mimic swallowing or make the sound "eeee" it may help. Patients should be reassured that after the tube has been placed, they will usually adapt to it very soon and no longer notice it.

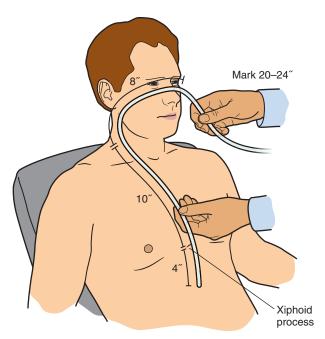

Before nasogastric tube removal, the patient should be informed of the procedure and what to expect. Towels, surgical Chux, or other drapes should be placed around the patient's neck and chest. He or she should be handed an emesis basin and tissues.

## **TECHNIQUE**

Observe universal blood and body fluid precautions during the procedure. Wear gloves, goggles, a face mask, and an impervious gown.

- 1. Elevate the head of the bed into a high Fowler (sitting) position. Rest the back of the patient's head on a pillow or directly on the bed for support. The patient's clothing needs to be protected with a towel or surgical Chux. An emesis basin should be available on the patient's lap.
- 2. Check for a clear nasal passage. Various conditions may cause asymmetric nostril openings, for example, septal deviation, nasal polyps, septal spurs. So examine both nostrils to determine which is the largest and most open. You can also watch the patient inhaling through his or her nose to determine which nostril is more open.
- 3. Choose an optimal tube for the patient. A large-bore nasogastric tube (16 or 18 Fr), Salem sump (with antireflux valve, if available), or Levin tube should be used for adults. Select the largest tube possible for the patient's nostril size. The Salem sump tube has marks at 18, 22, 26, and 30 inches from the distal end. Measure the tube to fit the patient by holding the nasogastric tube above the patient, with the distal end 6 inches below the xiphoid process for a nasogastric tube and 8 to 10 inches for a nasoenteric tube; the proximal end extended to the nose. Loop the mid-portion over the patient's earlobe. Note the tube marks based on these measurements or mark the

**Figure 203-4** Measuring the length of nasogastric tube for placement into stomach.

tube with a piece of tape to avoid inserting the tube too far (Fig. 203-4). The nasogastric tube should generally be secured with the 20- to 24-inch mark at the nasal vestibule.

4. After application of a nasal decongestant such as phenylephrine or oxymetazoline, adding a topical anesthetic usually increases the patient's comfort. Although this procedure is usually brief, application of the decongestant before the anesthesia usually results in the anesthesia lasting longer. The decongestant may also may minimize damage to the nasal mucosa and decrease the incidence of epistaxis.

NOTE: A randomized, controlled trial (Singer and Konia, 1999) showed improved comfort when a decongestant/ anesthetic was used, compared with plain lubrication for nasogastric tube insertion. In the study, topical anesthesia was applied (after the decongestant) by injecting 5 mL of 2% lidocaine gel (Xylocaine Jelly) into the nostril before insertion. The pharynx was then sprayed with both benzocaine (Hurricaine) and tetracaine hydrochloride (Cetacaine) spray to minimize the gag reflex. If possible, allow time for the decongestants and anesthetics to take effect before inserting the tube. Topical cocaine solution can also be used, but it often causes a strong burning sensation on application (see Equipment section for other warnings). Application of topical anesthesia should be considered the standard of care except in emergency situations where adequate lubrication alone may be acceptable.

- 5. An alternative option is to lubricate a soft nasal airway with 2% lidocaine gel and allow the patient to insert the lubricated airway into his or her nares. The nasogastric tube can then be inserted through the soft airway. As the patient swallows the gel, it will anesthetize the pharynx. A soft airway not only minimizes patient discomfort, it can also decrease the risk of severe epistaxis, intracranial intubation, and kinking of the nasogastric tube into the mouth.
- Lubricate the tip of the tube with additional anesthetic jelly or a water-soluble lubricant. Curl the tube by rolling 18 to 20 inches of the distal tube clockwise onto the first three fingers of your nondominant hand.

- 7. Introduce the lubricated tube tip into the nostril, pointing straight to the back of the nasal cavity and toward the base of the skull (Fig. 203-5). Recalling the anatomy, it should be inserted horizontally, along the floor of the nasal passage, and directed straight back, not upward. Feed the tube slowly with the dominant hand into the nostril using continuous movement while unrolling the curled tube with the nondominant hand. The patient can sniff to assist the insertion. Never force a tube against resistance; however, spinning or twisting the tube slightly may help overcome resistance.
- 8. Have the patient flex his or her head slightly forward to narrow the pharyngeal airway. When the tip of the tube reaches the nasopharynx a slight increase in resistance will be noted (Fig. 203-6). Continue to advance the tube, and when the resistance decreases again, ask the patient to swallow or drink some water with a straw. Continue to push the tube with the same motion while asking the patient to continue swallowing. If the patient starts coughing or becomes distressed, or fog is seen in the tube, the tube has probably entered the trachea. The tube should be withdrawn a few inches, but not entirely, twisted slightly, and the process started again. If a patient cannot swallow, it is also helpful to mimic swallowing or to make the sound "eeee."
- 9. Continue to push the tube until the desired mark is reached if the patient is not coughing. In adults, this is slightly past the 22-inch mark—the second mark—on a Salem sump tube. The gastroesophageal junction is usually about 16 to 18 inches from the nose—the first mark—and the tube should be inserted about 4 inches beyond the gastroesophageal junction. If the stomach is full, an immediate return of fluid may occur. Use the emesis basin to collect this. If there is no return of fluid, open the patient's mouth to confirm that the tube is not curled in the mouth or pharynx.

**NOTE:** If significant resistance, respiratory distress, or a nasal hemorrhage occurs, or the patient suddenly becomes unable to speak, the tube should be withdrawn.

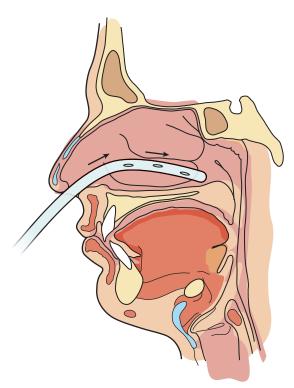

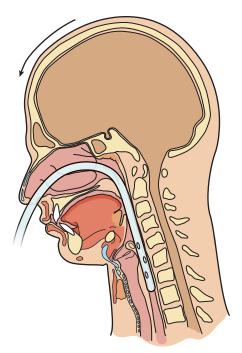

Figure 203-5 Horizontal insertion of nasogastric tube into nasopharynx.

**Figure 203-6** Have the patient flex his or her head. Next, gently advance the tube while asking the patient to swallow.

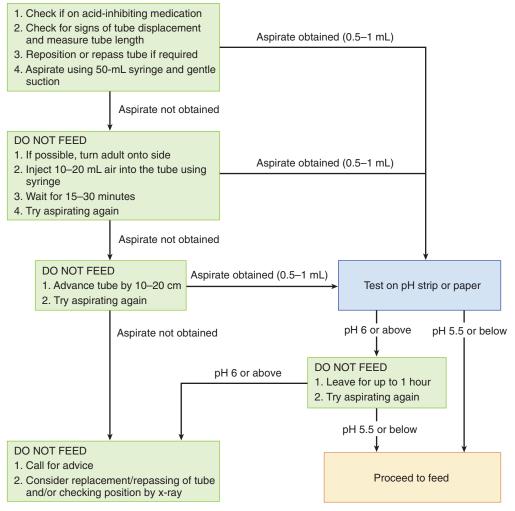

- 10a. Extra steps to facilitate placement of a *nasoenteric feeding tube* include the following:
  - Having placed the tube into the stomach, leave some extra tubing or slack to facilitate passage of the tip into the duodenum.
  - Place the patient in a right lateral decubitus (right side down) position.
  - A 60-mL syringe (Toomey) can be used to inject 400 mL of air to distend the stomach. This may allow a feeding tube coiled in the fundus of the stomach to uncoil and pass more freely into the duodenum.
  - In refractory cases, metoclopramide (Reglan) 10 mg may be given intravenously, with or without erythromycin 250 mg intravenously, to increase gastric motility.
- 10b. Extra steps to facilitate any tube placement include the following:
  - If the tube persistently kinks or coils into the mouth, cooling the tube in ice chips or a refrigerator for 5 minutes may stiffen it to prevent coiling. A larger-bore tube is also less likely to coil.
